Everything you need to know about Django.

### 1.1 Getting help

Having trouble? We'd like to help!

- Try the [FAQ](#) – it's got answers to many common questions.
- Looking for specific information? Try the [genindex](#), [modindex](#) or the [detailed table of contents](#).
- Search for information in the archives of the [django-users](#) mailing list, or [post a question](#).
- Ask a question in the [#django IRC channel](#), or search the [IRC logs](#) to see if it's been asked before.
- Report bugs with Django in our [ticket tracker](#).

### 1.2 How the documentation is organized

Django has a lot of documentation. A high-level overview of how it's organized will help you know where to look for certain things:

- [Tutorials](#) take you by the hand through a series of steps to create a Web application. Start here if you're new to Django or Web application development. Also look at the "[First steps](#)" below.
- [Topic guides](#) discuss key topics and concepts at a fairly high level and provide useful background information and explanation.
- [Reference guides](#) contain technical reference for APIs and other aspects of Django's machinery. They describe how it works and how to use it but assume that you have a basic understanding of key concepts.
- [How-to guides](#) are recipes. They guide you through the steps involved in addressing key problems and use-cases. They are more advanced than tutorials and assume some knowledge of how Django works.

## 1.3 First steps

Are you new to Django or to programming? This is the place to start!

- **From scratch:** [Overview](#) | [Installation](#)
- **Tutorial:** [Part 1: Requests and responses](#) | [Part 2: Models and the admin site](#) | [Part 3: Views and templates](#) | [Part 4: Forms and generic views](#) | [Part 5: Testing](#) | [Part 6: Static files](#) | [Part 7: Customizing the admin site](#)
- **Advanced Tutorials:** [How to write reusable apps](#) | [Writing your first patch for Django](#)

## 1.4 The model layer

Django provides an abstraction layer (the “models”) for structuring and manipulating the data of your Web application. Learn more about it below:

- **Models:** [Introduction to models](#) | [Field types](#) | [Meta options](#) | [Model class](#)
- **QuerySets:** [Executing queries](#) | [QuerySet method reference](#) | [Lookup expressions](#)
- **Model instances:** [Instance methods](#) | [Accessing related objects](#)
- **Migrations:** [Introduction to Migrations](#) | [Operations reference](#) | [SchemaEditor](#) | [Writing migrations](#)
- **Advanced:** [Managers](#) | [Raw SQL](#) | [Transactions](#) | [Aggregation](#) | [Search](#) | [Custom fields](#) | [Multiple databases](#) | [Custom lookups](#) | [Query Expressions](#) | [Conditional Expressions](#) | [Database Functions](#)
- **Other:** [Supported databases](#) | [Legacy databases](#) | [Providing initial data](#) | [Optimize database access](#) | [PostgreSQL specific features](#)

## 1.5 The view layer

Django has the concept of “views” to encapsulate the logic responsible for processing a user’s request and for returning the response. Find all you need to know about views via the links below:

- **The basics:** [URLconfs](#) | [View functions](#) | [Shortcuts](#) | [Decorators](#)
- **Reference:** [Built-in Views](#) | [Request/response objects](#) | [TemplateResponse objects](#)
- **File uploads:** [Overview](#) | [File objects](#) | [Storage API](#) | [Managing files](#) | [Custom storage](#)
- **Class-based views:** [Overview](#) | [Built-in display views](#) | [Built-in editing views](#) | [Using mixins](#) | [API reference](#) | [Flattened index](#)
- **Advanced:** [Generating CSV](#) | [Generating PDF](#)
- **Middleware:** [Overview](#) | [Built-in middleware classes](#)

## 1.6 The template layer

The template layer provides a designer-friendly syntax for rendering the information to be presented to the user. Learn how this syntax can be used by designers and how it can be extended by programmers:

- **The basics:** [Overview](#)
- **For designers:** [Language overview](#) | [Built-in tags and filters](#) | [Humanization](#)

- **For programmers:** *Template API | Custom tags and filters*

## 1.7 Forms

Django provides a rich framework to facilitate the creation of forms and the manipulation of form data.

- **The basics:** *Overview | Form API | Built-in fields | Built-in widgets*
- **Advanced:** *Forms for models | Integrating media | Formsets | Customizing validation*

## 1.8 The development process

Learn about the various components and tools to help you in the development and testing of Django applications:

- **Settings:** *Overview | Full list of settings*
- **Applications:** *Overview*
- **Exceptions:** *Overview*
- **django-admin and manage.py:** *Overview | Adding custom commands*
- **Testing:** *Introduction | Writing and running tests | Included testing tools | Advanced topics*
- **Deployment:** *Overview | WSGI servers | Deploying static files | Tracking code errors by email*

## 1.9 The admin

Find all you need to know about the automated admin interface, one of Django's most popular features:

- *Admin site*
- *Admin actions*
- *Admin documentation generator*

## 1.10 Security

Security is a topic of paramount importance in the development of Web applications and Django provides multiple protection tools and mechanisms:

- *Security overview*
- *Disclosed security issues in Django*
- *Clickjacking protection*
- *Cross Site Request Forgery protection*
- *Cryptographic signing*
- *Security Middleware*

## 1.11 Internationalization and localization

Django offers a robust internationalization and localization framework to assist you in the development of applications for multiple languages and world regions:

- *Overview | Internationalization | Localization | Localized Web UI formatting and form input*
- *Time zones*

## 1.12 Performance and optimization

There are a variety of techniques and tools that can help get your code running more efficiently - faster, and using fewer system resources.

- *Performance and optimization overview*

## 1.13 Python compatibility

Django aims to be compatible with multiple different flavors and versions of Python:

- *Python support*
- *Python 3 compatibility*

## 1.14 Geographic framework

*GeoDjango* intends to be a world-class geographic Web framework. Its goal is to make it as easy as possible to build GIS Web applications and harness the power of spatially enabled data.

## 1.15 Common Web application tools

Django offers multiple tools commonly needed in the development of Web applications:

- **Authentication:** *Overview | Using the authentication system | Password management | Customizing authentication | API Reference*
- *Caching*
- *Logging*
- *Sending emails*
- *Syndication feeds (RSS/Atom)*
- *Pagination*
- *Messages framework*
- *Serialization*
- *Sessions*
- *Sitemaps*
- *Static files management*

- *Data validation*

## 1.16 Other core functionalities

Learn about some other core functionalities of the Django framework:

- *Conditional content processing*
- *Content types and generic relations*
- *Flatpages*
- *Redirects*
- *Signals*
- *System check framework*
- *The sites framework*
- *Unicode in Django*

## 1.17 The Django open-source project

Learn about the development process for the Django project itself and about how you can contribute:

- **Community:** *How to get involved* | *The release process* | *Team organization* | *Meet the team* | *Current roles* | *The Django source code repository* | *Security policies* | *Mailing lists*
- **Design philosophies:** *Overview*
- **Documentation:** *About this documentation*
- **Third-party distributions:** *Overview*
- **Django over time:** *API stability* | *Release notes and upgrading instructions* | *Deprecation Timeline*

New to Django? Or to Web development in general? Well, you came to the right place: read this material to quickly get up and running.

## 2.1 Django at a glance

Because Django was developed in a fast-paced newsroom environment, it was designed to make common Web-development tasks fast and easy. Here's an informal overview of how to write a database-driven Web app with Django.

The goal of this document is to give you enough technical specifics to understand how Django works, but this isn't intended to be a tutorial or reference – but we've got both! When you're ready to start a project, you can *start with the tutorial* or *dive right into more detailed documentation*.

### 2.1.1 Design your model

Although you can use Django without a database, it comes with an **object-relational mapper** in which you describe your database layout in Python code.

The *data-model syntax* offers many rich ways of representing your models – so far, it's been solving many years' worth of database-schema problems. Here's a quick example:

```
mysite/news/models.py

from django.db import models

class Reporter(models.Model):
    full_name = models.CharField(max_length=70)

    def __str__(self):
        # __unicode__ on Python 2
        return self.full_name

class Article(models.Model):
    pub_date = models.DateField()
    headline = models.CharField(max_length=200)
```

```
content = models.TextField()
reporter = models.ForeignKey(Reporter, on_delete=models.CASCADE)

def __str__(self):
    # __unicode__ on Python 2
    return self.headline
```

## 2.1.2 Install it

Next, run the Django command-line utility to create the database tables automatically:

```
$ python manage.py migrate
```

The `migrate` command looks at all your available models and creates tables in your database for whichever tables don't already exist, as well as optionally providing *much richer schema control*.

## 2.1.3 Enjoy the free API

With that, you've got a free, and rich, *Python API* to access your data. The API is created on the fly, no code generation necessary:

```
# Import the models we created from our "news" app
>>> from news.models import Reporter, Article

# No reporters are in the system yet.
>>> Reporter.objects.all()
<QuerySet []>

# Create a new Reporter.
>>> r = Reporter(full_name='John Smith')

# Save the object into the database. You have to call save() explicitly.
>>> r.save()

# Now it has an ID.
>>> r.id
1

# Now the new reporter is in the database.
>>> Reporter.objects.all()
<QuerySet [<Reporter: John Smith>]>

# Fields are represented as attributes on the Python object.
>>> r.full_name
'John Smith'

# Django provides a rich database lookup API.
>>> Reporter.objects.get(id=1)
<Reporter: John Smith>
>>> Reporter.objects.get(full_name__startswith='John')
<Reporter: John Smith>
>>> Reporter.objects.get(full_name__contains='mith')
<Reporter: John Smith>
>>> Reporter.objects.get(id=2)
Traceback (most recent call last):
...
DoesNotExist: Reporter matching query does not exist.
```

```

# Create an article.
>>> from datetime import date
>>> a = Article(pub_date=date.today(), headline='Django is cool',
...            content='Yeah.', reporter=r)
>>> a.save()

# Now the article is in the database.
>>> Article.objects.all()
<QuerySet [ <Article: Django is cool > ]>

# Article objects get API access to related Reporter objects.
>>> r = a.reporter
>>> r.full_name
'John Smith'

# And vice versa: Reporter objects get API access to Article objects.
>>> r.article_set.all()
<QuerySet [ <Article: Django is cool > ]>

# The API follows relationships as far as you need, performing efficient
# JOINS for you behind the scenes.
# This finds all articles by a reporter whose name starts with "John".
>>> Article.objects.filter(reporter__full_name__startswith='John')
<QuerySet [ <Article: Django is cool > ]>

# Change an object by altering its attributes and calling save().
>>> r.full_name = 'Billy Goat'
>>> r.save()

# Delete an object with delete().
>>> r.delete()

```

## 2.1.4 A dynamic admin interface: it's not just scaffolding – it's the whole house

Once your models are defined, Django can automatically create a professional, production ready *administrative interface* – a website that lets authenticated users add, change and delete objects. It's as easy as registering your model in the admin site:

```
mysite/news/models.py
```

```

from django.db import models

class Article(models.Model):
    pub_date = models.DateField()
    headline = models.CharField(max_length=200)
    content = models.TextField()
    reporter = models.ForeignKey(Reporter, on_delete=models.CASCADE)

```

```
mysite/news/admin.py
```

```

from django.contrib import admin

from . import models

admin.site.register(models.Article)

```

The philosophy here is that your site is edited by a staff, or a client, or maybe just you – and you don’t want to have to deal with creating backend interfaces just to manage content.

One typical workflow in creating Django apps is to create models and get the admin sites up and running as fast as possible, so your staff (or clients) can start populating data. Then, develop the way data is presented to the public.

## 2.1.5 Design your URLs

A clean, elegant URL scheme is an important detail in a high-quality Web application. Django encourages beautiful URL design and doesn’t put any cruft in URLs, like `.php` or `.asp`.

To design URLs for an app, you create a Python module called a *URLconf*. A table of contents for your app, it contains a simple mapping between URL patterns and Python callback functions. URLconfs also serve to decouple URLs from Python code.

Here’s what a URLconf might look like for the `Reporter/Article` example above:

```
mysite/news/urls.py

from django.conf.urls import url

from . import views

urlpatterns = [
    url(r'^articles/([0-9]{4})/$', views.year_archive),
    url(r'^articles/([0-9]{4})/([0-9]{2})/$', views.month_archive),
    url(r'^articles/([0-9]{4})/([0-9]{2})/([0-9]+)/$', views.article_detail),
]
```

The code above maps URLs, as simple [regular expressions](#), to the location of Python callback functions (“views”). The regular expressions use parenthesis to “capture” values from the URLs. When a user requests a page, Django runs through each pattern, in order, and stops at the first one that matches the requested URL. (If none of them matches, Django calls a special-case 404 view.) This is blazingly fast, because the regular expressions are compiled at load time.

Once one of the regexes matches, Django imports and calls the given view, which is a simple Python function. Each view gets passed a request object – which contains request metadata – and the values captured in the regex.

For example, if a user requested the URL `“/articles/2005/05/39323/”`, Django would call the function `news.views.article_detail(request, '2005', '05', '39323')`.

## 2.1.6 Write your views

Each view is responsible for doing one of two things: Returning an *HttpResponse* object containing the content for the requested page, or raising an exception such as *Http404*. The rest is up to you.

Generally, a view retrieves data according to the parameters, loads a template and renders the template with the retrieved data. Here’s an example view for `year_archive` from above:

```
mysite/news/views.py

from django.shortcuts import render

from .models import Article

def year_archive(request, year):
    a_list = Article.objects.filter(pub_date__year=year)
    context = {'year': year, 'article_list': a_list}
    return render(request, 'news/year_archive.html', context)
```

This example uses Django’s *template system*, which has several powerful features but strives to stay simple enough for non-programmers to use.

## 2.1.7 Design your templates

The code above loads the `news/year_archive.html` template.

Django has a template search path, which allows you to minimize redundancy among templates. In your Django settings, you specify a list of directories to check for templates with `DIRS`. If a template doesn’t exist in the first directory, it checks the second, and so on.

Let’s say the `news/year_archive.html` template was found. Here’s what that might look like:

```
mysite/news/templates/news/year_archive.html
{% extends "base.html" %}

{% block title %}Articles for {{ year }}{% endblock %}

{% block content %}
<h1>Articles for {{ year }}</h1>

{% for article in article_list %}
  <p>{{ article.headline }}</p>
  <p>By {{ article.reporter.full_name }}</p>
  <p>Published {{ article.pub_date|date:"F j, Y" }}</p>
{% endfor %}
{% endblock %}
```

Variables are surrounded by double-curly braces. `{{ article.headline }}` means “Output the value of the article’s headline attribute.” But dots aren’t used only for attribute lookup. They also can do dictionary-key lookup, index lookup and function calls.

Note `{{ article.pub_date|date:"F j, Y" }}` uses a Unix-style “pipe” (the “|” character). This is called a template filter, and it’s a way to filter the value of a variable. In this case, the date filter formats a Python datetime object in the given format (as found in PHP’s date function).

You can chain together as many filters as you’d like. You can write *custom template filters*. You can write *custom template tags*, which run custom Python code behind the scenes.

Finally, Django uses the concept of “template inheritance”. That’s what the `{% extends "base.html" %}` does. It means “First load the template called ‘base’, which has defined a bunch of blocks, and fill the blocks with the following blocks.” In short, that lets you dramatically cut down on redundancy in templates: each template has to define only what’s unique to that template.

Here’s what the “base.html” template, including the use of *static files*, might look like:

```
mysite/templates/base.html

{% load static %}
<html>
<head>
  <title>{% block title %}{% endblock %}</title>
</head>
<body>
  
  {% block content %}{% endblock %}
</body>
</html>
```

Simplistically, it defines the look-and-feel of the site (with the site’s logo), and provides “holes” for child templates to fill. This makes a site redesign as easy as changing a single file – the base template.

It also lets you create multiple versions of a site, with different base templates, while reusing child templates. Django’s creators have used this technique to create strikingly different mobile versions of sites – simply by creating a new base template.

Note that you don’t have to use Django’s template system if you prefer another system. While Django’s template system is particularly well-integrated with Django’s model layer, nothing forces you to use it. For that matter, you don’t have to use Django’s database API, either. You can use another database abstraction layer, you can read XML files, you can read files off disk, or anything you want. Each piece of Django – models, views, templates – is decoupled from the next.

## 2.1.8 This is just the surface

This has been only a quick overview of Django’s functionality. Some more useful features:

- A *caching framework* that integrates with memcached or other backends.
- A *syndication framework* that makes creating RSS and Atom feeds as easy as writing a small Python class.
- More sexy automatically-generated admin features – this overview barely scratched the surface.

The next obvious steps are for you to [download Django](#), read *the tutorial* and join [the community](#). Thanks for your interest!

## 2.2 Quick install guide

Before you can use Django, you’ll need to get it installed. We have a *complete installation guide* that covers all the possibilities; this guide will guide you to a simple, minimal installation that’ll work while you walk through the introduction.

### 2.2.1 Install Python

Being a Python Web framework, Django requires Python. See *What Python version can I use with Django?* for details. Python includes a lightweight database called *SQLite* so you won’t need to set up a database just yet.

Get the latest version of Python at <https://www.python.org/download/> or with your operating system’s package manager.

---

#### Django on Jython

If you use *Jython* (a Python implementation for the Java platform), you’ll need to follow a few additional steps. See *Running Django on Jython* for details.

---

You can verify that Python is installed by typing `python` from your shell; you should see something like:

```
Python 3.4.x
[GCC 4.x] on linux
Type "help", "copyright", "credits" or "license" for more information.
>>>
```

## 2.2.2 Set up a database

This step is only necessary if you'd like to work with a “large” database engine like PostgreSQL, MySQL, or Oracle. To install such a database, consult the *database installation information*.

## 2.2.3 Remove any old versions of Django

If you are upgrading your installation of Django from a previous version, you will need to *uninstall the old Django version before installing the new version*.

## 2.2.4 Install Django

You've got three easy options to install Django:

- *Install an official release*. This is the best approach for most users.
- Install a version of Django *provided by your operating system distribution*.
- *Install the latest development version*. This option is for enthusiasts who want the latest-and-greatest features and aren't afraid of running brand new code. You might encounter new bugs in the development version, but reporting them helps the development of Django. Also, releases of third-party packages are less likely to be compatible with the development version than with the latest stable release.

---

**Always refer to the documentation that corresponds to the version of Django you're using!**

If you do either of the first two steps, keep an eye out for parts of the documentation marked **new in development version**. That phrase flags features that are only available in development versions of Django, and they likely won't work with an official release.

---

## 2.2.5 Verifying

To verify that Django can be seen by Python, type `python` from your shell. Then at the Python prompt, try to import Django:

```
>>> import django
>>> print(django.get_version())
1.10
```

You may have another version of Django installed.

## 2.2.6 That's it!

That's it – you can now *move onto the tutorial*.

## 2.3 Writing your first Django app, part 1

Let's learn by example.

Throughout this tutorial, we'll walk you through the creation of a basic poll application.

It'll consist of two parts:

- A public site that lets people view polls and vote in them.
- An admin site that lets you add, change, and delete polls.

We'll assume you have *Django installed* already. You can tell Django is installed and which version by running the following command:

```
$ python -m django --version
```

If Django is installed, you should see the version of your installation. If it isn't, you'll get an error telling "No module named django".

This tutorial is written for Django 1.10 and Python 3.4 or later. If the Django version doesn't match, you can refer to the tutorial for your version of Django by using the version switcher at the bottom right corner of this page, or update Django to the newest version. If you are still using Python 2.7, you will need to adjust the code samples slightly, as described in comments.

See *How to install Django* for advice on how to remove older versions of Django and install a newer one.

---

### Where to get help:

If you're having trouble going through this tutorial, please post a message to [django-users](#) or drop by [#django](#) on [irc.freenode.net](#) to chat with other Django users who might be able to help.

---

## 2.3.1 Creating a project

If this is your first time using Django, you'll have to take care of some initial setup. Namely, you'll need to auto-generate some code that establishes a Django *project* – a collection of settings for an instance of Django, including database configuration, Django-specific options and application-specific settings.

From the command line, `cd` into a directory where you'd like to store your code, then run the following command:

```
$ django-admin startproject mysite
```

This will create a `mysite` directory in your current directory. If it didn't work, see *Problems running django-admin*.

---

**Note:** You'll need to avoid naming projects after built-in Python or Django components. In particular, this means you should avoid using names like `django` (which will conflict with Django itself) or `test` (which conflicts with a built-in Python package).

---

### Where should this code live?

If your background is in plain old PHP (with no use of modern frameworks), you're probably used to putting code under the Web server's document root (in a place such as `/var/www`). With Django, you don't do that. It's not a good idea to put any of this Python code within your Web server's document root, because it risks the possibility that people may be able to view your code over the Web. That's not good for security.

Put your code in some directory **outside** of the document root, such as `/home/mycode`.

---

Let's look at what `startproject` created:

```
mysite/  
  manage.py  
  mysite/
```

```
__init__.py
settings.py
urls.py
wsgi.py
```

These files are:

- The outer `mysite/` root directory is just a container for your project. Its name doesn't matter to Django; you can rename it to anything you like.
- `manage.py`: A command-line utility that lets you interact with this Django project in various ways. You can read all the details about `manage.py` in *django-admin and manage.py*.
- The inner `mysite/` directory is the actual Python package for your project. Its name is the Python package name you'll need to use to import anything inside it (e.g. `mysite.urls`).
- `mysite/__init__.py`: An empty file that tells Python that this directory should be considered a Python package. If you're a Python beginner, read [more about packages](#) in the official Python docs.
- `mysite/settings.py`: Settings/configuration for this Django project. *Django settings* will tell you all about how settings work.
- `mysite/urls.py`: The URL declarations for this Django project; a “table of contents” of your Django-powered site. You can read more about URLs in *URL dispatcher*.
- `mysite/wsgi.py`: An entry-point for WSGI-compatible web servers to serve your project. See *How to deploy with WSGI* for more details.

### 2.3.2 The development server

Let's verify your Django project works. Change into the outer `mysite` directory, if you haven't already, and run the following commands:

```
$ python manage.py runserver
```

You'll see the following output on the command line:

```
Performing system checks...
```

```
System check identified no issues (0 silenced).
```

```
You have unapplied migrations; your app may not work properly until they are_
↪applied.
```

```
Run 'python manage.py migrate' to apply them.
```

```
November 23, 2017 - 15:50:53
```

```
Django version 1.10, using settings 'mysite.settings'
```

```
Starting development server at http://127.0.0.1:8000/
```

```
Quit the server with CONTROL-C.
```

---

**Note:** Ignore the warning about unapplied database migrations for now; we'll deal with the database shortly.

---

You've started the Django development server, a lightweight Web server written purely in Python. We've included this with Django so you can develop things rapidly, without having to deal with configuring a production server – such as Apache – until you're ready for production.

Now's a good time to note: **don't** use this server in anything resembling a production environment. It's intended only for use while developing. (We're in the business of making Web frameworks, not Web servers.)

Now that the server's running, visit <http://127.0.0.1:8000/> with your Web browser. You'll see a "Welcome to Django" page, in pleasant, light-blue pastel. It worked!

---

### Changing the port

By default, the `runserver` command starts the development server on the internal IP at port 8000.

If you want to change the server's port, pass it as a command-line argument. For instance, this command starts the server on port 8080:

```
$ python manage.py runserver 8080
```

If you want to change the server's IP, pass it along with the port. So to listen on all public IPs (useful if you want to show off your work on other computers on your network), use:

```
$ python manage.py runserver 0.0.0.0:8000
```

Full docs for the development server can be found in the `runserver` reference.

---

### Automatic reloading of `runserver`

The development server automatically reloads Python code for each request as needed. You don't need to restart the server for code changes to take effect. However, some actions like adding files don't trigger a restart, so you'll have to restart the server in these cases.

---

## 2.3.3 Creating the Polls app

Now that your environment – a "project" – is set up, you're set to start doing work.

Each application you write in Django consists of a Python package that follows a certain convention. Django comes with a utility that automatically generates the basic directory structure of an app, so you can focus on writing code rather than creating directories.

---

### Projects vs. apps

What's the difference between a project and an app? An app is a Web application that does something – e.g., a Weblog system, a database of public records or a simple poll app. A project is a collection of configuration and apps for a particular website. A project can contain multiple apps. An app can be in multiple projects.

---

Your apps can live anywhere on your `Python path`. In this tutorial, we'll create our poll app right next to your `manage.py` file so that it can be imported as its own top-level module, rather than a submodule of `mysite`.

To create your app, make sure you're in the same directory as `manage.py` and type this command:

```
$ python manage.py startapp polls
```

That'll create a directory `polls`, which is laid out like this:

```
polls/  
  __init__.py  
  admin.py
```

```

apps.py
migrations/
    __init__.py
models.py
tests.py
views.py

```

This directory structure will house the poll application.

### 2.3.4 Write your first view

Let's write the first view. Open the file `polls/views.py` and put the following Python code in it:

```
polls/views.py
```

```
from django.http import HttpResponse
```

```
def index(request):
    return HttpResponse("Hello, world. You're at the polls index.")
```

This is the simplest view possible in Django. To call the view, we need to map it to a URL - and for this we need a `URLconf`.

To create a `URLconf` in the `polls` directory, create a file called `urls.py`. Your app directory should now look like:

```

polls/
    __init__.py
    admin.py
    apps.py
    migrations/
        __init__.py
    models.py
    tests.py
    urls.py
    views.py

```

In the `polls/urls.py` file include the following code:

```
polls/urls.py
```

```

from django.conf.urls import url

from . import views

urlpatterns = [
    url(r'^$', views.index, name='index'),
]

```

The next step is to point the root `URLconf` at the `polls.urls` module. In `mysite/urls.py`, add an import for `django.conf.urls.include` and insert an `include()` in the `urlpatterns` list, so you have:

```
mysite/urls.py
```

```

from django.conf.urls import include, url
from django.contrib import admin

urlpatterns = [
    url(r'^polls/', include('polls.urls')),
]

```

```
    url(r'^admin/', admin.site.urls),  
]
```

The `include()` function allows referencing other URLconfs. Note that the regular expressions for the `include()` function doesn't have a `$` (end-of-string match character) but rather a trailing slash. Whenever Django encounters `include()`, it chops off whatever part of the URL matched up to that point and sends the remaining string to the included URLconf for further processing.

The idea behind `include()` is to make it easy to plug-and-play URLs. Since polls are in their own URLconf (`polls/urls.py`), they can be placed under `"/polls/"`, or under `"/fun_polls/"`, or under `"/content/polls/"`, or any other path root, and the app will still work.

---

### When to use `include()`

You should always use `include()` when you include other URL patterns. `admin.site.urls` is the only exception to this.

---

### Doesn't match what you see?

If you're seeing `include(admin.site.urls)` instead of just `admin.site.urls`, you're probably using a version of Django that doesn't match this tutorial version. You'll want to either switch to the older tutorial or the newer Django version.

---

You have now wired an `index` view into the URLconf. Lets verify it's working, run the following command:

```
$ python manage.py runserver
```

Go to <http://localhost:8000/polls/> in your browser, and you should see the text *"Hello, world. You're at the polls index."*, which you defined in the `index` view.

The `url()` function is passed four arguments, two required: `regex` and `view`, and two optional: `kwargs`, and `name`. At this point, it's worth reviewing what these arguments are for.

### `url()` argument: `regex`

The term "regex" is a commonly used short form meaning "regular expression", which is a syntax for matching patterns in strings, or in this case, url patterns. Django starts at the first regular expression and makes its way down the list, comparing the requested URL against each regular expression until it finds one that matches.

Note that these regular expressions do not search GET and POST parameters, or the domain name. For example, in a request to `https://www.example.com/myapp/`, the URLconf will look for `myapp/`. In a request to `https://www.example.com/myapp/?page=3`, the URLconf will also look for `myapp/`.

If you need help with regular expressions, see [Wikipedia's entry](#) and the documentation of the `re` module. Also, the O'Reilly book "Mastering Regular Expressions" by Jeffrey Friedl is fantastic. In practice, however, you don't need to be an expert on regular expressions, as you really only need to know how to capture simple patterns. In fact, complex regexes can have poor lookup performance, so you probably shouldn't rely on the full power of regexes.

Finally, a performance note: these regular expressions are compiled the first time the URLconf module is loaded. They're super fast (as long as the lookups aren't too complex as noted above).

### `url()` argument: `view`

When Django finds a regular expression match, Django calls the specified view function, with an `HttpRequest` object as the first argument and any "captured" values from the regular expression as other arguments. If the regex

uses simple captures, values are passed as positional arguments; if it uses named captures, values are passed as keyword arguments. We'll give an example of this in a bit.

### `url()` argument: `kwargs`

Arbitrary keyword arguments can be passed in a dictionary to the target view. We aren't going to use this feature of Django in the tutorial.

### `url()` argument: `name`

Naming your URL lets you refer to it unambiguously from elsewhere in Django, especially from within templates. This powerful feature allows you to make global changes to the URL patterns of your project while only touching a single file.

When you're comfortable with the basic request and response flow, read [part 2 of this tutorial](#) to start working with the database.

## 2.4 Writing your first Django app, part 2

This tutorial begins where [Tutorial 1](#) left off. We'll setup the database, create your first model, and get a quick introduction to Django's automatically-generated admin site.

### 2.4.1 Database setup

Now, open up `mysite/settings.py`. It's a normal Python module with module-level variables representing Django settings.

By default, the configuration uses SQLite. If you're new to databases, or you're just interested in trying Django, this is the easiest choice. SQLite is included in Python, so you won't need to install anything else to support your database. When starting your first real project, however, you may want to use a more scalable database like PostgreSQL, to avoid database-switching headaches down the road.

If you wish to use another database, install the appropriate [database bindings](#) and change the following keys in the `DATABASES` 'default' item to match your database connection settings:

- `ENGINE` – Either `'django.db.backends.sqlite3'`, `'django.db.backends.postgresql'`, `'django.db.backends.mysql'`, or `'django.db.backends.oracle'`. Other backends are *also available*.
- `NAME` – The name of your database. If you're using SQLite, the database will be a file on your computer; in that case, `NAME` should be the full absolute path, including filename, of that file. The default value, `os.path.join(BASE_DIR, 'db.sqlite3')`, will store the file in your project directory.

If you are not using SQLite as your database, additional settings such as `USER`, `PASSWORD`, and `HOST` must be added. For more details, see the reference documentation for `DATABASES`.

---

#### For databases other than SQLite

If you're using a database besides SQLite, make sure you've created a database by this point. Do that with `"CREATE DATABASE database_name;"` within your database's interactive prompt.

Also make sure that the database user provided in `mysite/settings.py` has "create database" privileges. This allows automatic creation of a *test database* which will be needed in a later tutorial.

If you're using SQLite, you don't need to create anything beforehand - the database file will be created automatically when it is needed.

---

While you're editing `mysite/settings.py`, set `TIME_ZONE` to your time zone.

Also, note the `INSTALLED_APPS` setting at the top of the file. That holds the names of all Django applications that are activated in this Django instance. Apps can be used in multiple projects, and you can package and distribute them for use by others in their projects.

By default, `INSTALLED_APPS` contains the following apps, all of which come with Django:

- `django.contrib.admin` – The admin site. You'll use it shortly.
- `django.contrib.auth` – An authentication system.
- `django.contrib.contenttypes` – A framework for content types.
- `django.contrib.sessions` – A session framework.
- `django.contrib.messages` – A messaging framework.
- `django.contrib.staticfiles` – A framework for managing static files.

These applications are included by default as a convenience for the common case.

Some of these applications make use of at least one database table, though, so we need to create the tables in the database before we can use them. To do that, run the following command:

```
$ python manage.py migrate
```

The `migrate` command looks at the `INSTALLED_APPS` setting and creates any necessary database tables according to the database settings in your `mysite/settings.py` file and the database migrations shipped with the app (we'll cover those later). You'll see a message for each migration it applies. If you're interested, run the command-line client for your database and type `\dt` (PostgreSQL), `SHOW TABLES;` (MySQL), `.schema` (SQLite), or `SELECT TABLE_NAME FROM USER_TABLES;` (Oracle) to display the tables Django created.

---

### For the minimalists

Like we said above, the default applications are included for the common case, but not everybody needs them. If you don't need any or all of them, feel free to comment-out or delete the appropriate line(s) from `INSTALLED_APPS` before running `migrate`. The `migrate` command will only run migrations for apps in `INSTALLED_APPS`.

---

## 2.4.2 Creating models

Now we'll define your models – essentially, your database layout, with additional metadata.

---

### Philosophy

A model is the single, definitive source of truth about your data. It contains the essential fields and behaviors of the data you're storing. Django follows the *DRY Principle*. The goal is to define your data model in one place and automatically derive things from it.

This includes the migrations - unlike in Ruby On Rails, for example, migrations are entirely derived from your models file, and are essentially just a history that Django can roll through to update your database schema to match your current models.

---

In our simple poll app, we'll create two models: `Question` and `Choice`. A `Question` has a question and a publication date. A `Choice` has two fields: the text of the choice and a vote tally. Each `Choice` is associated with a `Question`.

These concepts are represented by simple Python classes. Edit the `polls/models.py` file so it looks like this:

```
polls/models.py

from django.db import models

class Question(models.Model):
    question_text = models.CharField(max_length=200)
    pub_date = models.DateTimeField('date published')

class Choice(models.Model):
    question = models.ForeignKey(Question, on_delete=models.CASCADE)
    choice_text = models.CharField(max_length=200)
    votes = models.IntegerField(default=0)
```

The code is straightforward. Each model is represented by a class that subclasses `django.db.models.Model`. Each model has a number of class variables, each of which represents a database field in the model.

Each field is represented by an instance of a *Field* class – e.g., `CharField` for character fields and `DateTimeField` for datetimes. This tells Django what type of data each field holds.

The name of each *Field* instance (e.g. `question_text` or `pub_date`) is the field's name, in machine-friendly format. You'll use this value in your Python code, and your database will use it as the column name.

You can use an optional first positional argument to a *Field* to designate a human-readable name. That's used in a couple of introspective parts of Django, and it doubles as documentation. If this field isn't provided, Django will use the machine-readable name. In this example, we've only defined a human-readable name for `Question.pub_date`. For all other fields in this model, the field's machine-readable name will suffice as its human-readable name.

Some *Field* classes have required arguments. `CharField`, for example, requires that you give it a `max_length`. That's used not only in the database schema, but in validation, as we'll soon see.

A *Field* can also have various optional arguments; in this case, we've set the `default` value of `votes` to 0.

Finally, note a relationship is defined, using `ForeignKey`. That tells Django each `Choice` is related to a single `Question`. Django supports all the common database relationships: many-to-one, many-to-many, and one-to-one.

### 2.4.3 Activating models

That small bit of model code gives Django a lot of information. With it, Django is able to:

- Create a database schema (CREATE TABLE statements) for this app.
- Create a Python database-access API for accessing `Question` and `Choice` objects.

But first we need to tell our project that the `polls` app is installed.

---

#### Philosophy

Django apps are “pluggable”: You can use an app in multiple projects, and you can distribute apps, because they don't have to be tied to a given Django installation.

---

To include the app in our project, we need to add a reference to its configuration class in the `INSTALLED_APPS` setting. The `PollsConfig` class is in the `polls/apps.py` file, so its dotted path is `'polls.apps.PollsConfig'`. Edit the `mysite/settings.py` file and add that dotted path to the `INSTALLED_APPS` setting. It'll look like this:

```
mysite/settings.py

INSTALLED_APPS = [
    'polls.apps.PollsConfig',
    'django.contrib.admin',
    'django.contrib.auth',
    'django.contrib.contenttypes',
    'django.contrib.sessions',
    'django.contrib.messages',
    'django.contrib.staticfiles',
]
```

Now Django knows to include the `polls` app. Let's run another command:

```
$ python manage.py makemigrations polls
```

You should see something similar to the following:

```
Migrations for 'polls':
  polls/migrations/0001_initial.py:
    - Create model Choice
    - Create model Question
    - Add field question to choice
```

By running `makemigrations`, you're telling Django that you've made some changes to your models (in this case, you've made new ones) and that you'd like the changes to be stored as a *migration*.

Migrations are how Django stores changes to your models (and thus your database schema) - they're just files on disk. You can read the migration for your new model if you like; it's the file `polls/migrations/0001_initial.py`. Don't worry, you're not expected to read them every time Django makes one, but they're designed to be human-editable in case you want to manually tweak how Django changes things.

There's a command that will run the migrations for you and manage your database schema automatically - that's called *migrate*, and we'll come to it in a moment - but first, let's see what SQL that migration would run. The `sqlmigrate` command takes migration names and returns their SQL:

```
$ python manage.py sqlmigrate polls 0001
```

You should see something similar to the following (we've reformatted it for readability):

```
BEGIN;
--
-- Create model Choice
--
CREATE TABLE "polls_choice" (
    "id" serial NOT NULL PRIMARY KEY,
    "choice_text" varchar(200) NOT NULL,
    "votes" integer NOT NULL
);
--
-- Create model Question
--
CREATE TABLE "polls_question" (
    "id" serial NOT NULL PRIMARY KEY,
    "question_text" varchar(200) NOT NULL,
```

```

    "pub_date" timestamp with time zone NOT NULL
);
--
-- Add field question to choice
--
ALTER TABLE "polls_choice" ADD COLUMN "question_id" integer NOT NULL;
ALTER TABLE "polls_choice" ALTER COLUMN "question_id" DROP DEFAULT;
CREATE INDEX "polls_choice_7aa0f6ee" ON "polls_choice" ("question_id");
ALTER TABLE "polls_choice"
    ADD CONSTRAINT "polls_choice_question_id_246c99a640fbbd72_fk_polls_question_id"
        FOREIGN KEY ("question_id")
        REFERENCES "polls_question" ("id")
        DEFERRABLE INITIALLY DEFERRED;

COMMIT;

```

Note the following:

- The exact output will vary depending on the database you are using. The example above is generated for PostgreSQL.
- Table names are automatically generated by combining the name of the app (`polls`) and the lowercase name of the model – `question` and `choice`. (You can override this behavior.)
- Primary keys (IDs) are added automatically. (You can override this, too.)
- By convention, Django appends `__id` to the foreign key field name. (Yes, you can override this, as well.)
- The foreign key relationship is made explicit by a `FOREIGN KEY` constraint. Don't worry about the `DEFERRABLE` parts; that's just telling PostgreSQL to not enforce the foreign key until the end of the transaction.
- It's tailored to the database you're using, so database-specific field types such as `auto_increment` (MySQL), `serial` (PostgreSQL), or `integer primary key autoincrement` (SQLite) are handled for you automatically. Same goes for the quoting of field names – e.g., using double quotes or single quotes.
- The `sqlmigrate` command doesn't actually run the migration on your database - it just prints it to the screen so that you can see what SQL Django thinks is required. It's useful for checking what Django is going to do or if you have database administrators who require SQL scripts for changes.

If you're interested, you can also run `python manage.py check`; this checks for any problems in your project without making migrations or touching the database.

Now, run `migrate` again to create those model tables in your database:

```

$ python manage.py migrate
Operations to perform:
  Apply all migrations: admin, auth, contenttypes, polls, sessions
Running migrations:
  Rendering model states... DONE
  Applying polls.0001_initial... OK

```

The `migrate` command takes all the migrations that haven't been applied (Django tracks which ones are applied using a special table in your database called `django_migrations`) and runs them against your database - essentially, synchronizing the changes you made to your models with the schema in the database.

Migrations are very powerful and let you change your models over time, as you develop your project, without the need to delete your database or tables and make new ones - it specializes in upgrading your database live, without losing data. We'll cover them in more depth in a later part of the tutorial, but for now, remember the three-step guide to making model changes:

- Change your models (in `models.py`).
- Run `python manage.py makemigrations` to create migrations for those changes
- Run `python manage.py migrate` to apply those changes to the database.

The reason that there are separate commands to make and apply migrations is because you'll commit migrations to your version control system and ship them with your app; they not only make your development easier, they're also useable by other developers and in production.

Read the [django-admin documentation](#) for full information on what the `manage.py` utility can do.

## 2.4.4 Playing with the API

Now, let's hop into the interactive Python shell and play around with the free API Django gives you. To invoke the Python shell, use this command:

```
$ python manage.py shell
```

We're using this instead of simply typing "python", because `manage.py` sets the `DJANGO_SETTINGS_MODULE` environment variable, which gives Django the Python import path to your `mysite/settings.py` file.

---

### Bypassing `manage.py`

If you'd rather not use `manage.py`, no problem. Just set the `DJANGO_SETTINGS_MODULE` environment variable to `mysite.settings`, start a plain Python shell, and set up Django:

```
>>> import django
>>> django.setup()
```

If this raises an `AttributeError`, you're probably using a version of Django that doesn't match this tutorial version. You'll want to either switch to the older tutorial or the newer Django version.

You must run `python` from the same directory `manage.py` is in, or ensure that directory is on the Python path, so that `import mysite` works.

For more information on all of this, see the [django-admin documentation](#).

---

Once you're in the shell, explore the [database API](#):

```
>>> from polls.models import Question, Choice # Import the model classes we just_
↳ wrote.

# No questions are in the system yet.
>>> Question.objects.all()
<QuerySet []>

# Create a new Question.
# Support for time zones is enabled in the default settings file, so
# Django expects a datetime with tzinfo for pub_date. Use timezone.now()
# instead of datetime.datetime.now() and it will do the right thing.
>>> from django.utils import timezone
>>> q = Question(question_text="What's new?", pub_date=timezone.now())

# Save the object into the database. You have to call save() explicitly.
>>> q.save()

# Now it has an ID. Note that this might say "1L" instead of "1", depending
```

```
# on which database you're using. That's no biggie; it just means your
# database backend prefers to return integers as Python long integer
# objects.
>>> q.id
1

# Access model field values via Python attributes.
>>> q.question_text
"What's new?"
>>> q.pub_date
datetime.datetime(2012, 2, 26, 13, 0, 0, 775217, tzinfo=<UTC>)

# Change values by changing the attributes, then calling save().
>>> q.question_text = "What's up?"
>>> q.save()

# objects.all() displays all the questions in the database.
>>> Question.objects.all()
<QuerySet [<Question: Question object>]>
```

Wait a minute. `<Question: Question object>` is, utterly, an unhelpful representation of this object. Let's fix that by editing the `Question` model (in the `polls/models.py` file) and adding a `__str__()` method to both `Question` and `Choice`:

```
polls/models.py
```

```
from django.db import models
from django.utils.encoding import python_2_unicode_compatible

@python_2_unicode_compatible # only if you need to support Python 2
class Question(models.Model):
    # ...
    def __str__(self):
        return self.question_text

@python_2_unicode_compatible # only if you need to support Python 2
class Choice(models.Model):
    # ...
    def __str__(self):
        return self.choice_text
```

It's important to add `__str__()` methods to your models, not only for your own convenience when dealing with the interactive prompt, but also because objects' representations are used throughout Django's automatically-generated admin.

Note these are normal Python methods. Let's add a custom method, just for demonstration:

```
polls/models.py
```

```
import datetime

from django.db import models
from django.utils import timezone

class Question(models.Model):
    # ...
    def was_published_recently(self):
        return self.pub_date >= timezone.now() - datetime.timedelta(days=1)
```

Note the addition of `import datetime` and `from django.utils import timezone`, to reference Python's standard `datetime` module and Django's time-zone-related utilities in `django.utils.timezone`, respectively. If you aren't familiar with time zone handling in Python, you can learn more in the [time zone support docs](#).

Save these changes and start a new Python interactive shell by running `python manage.py shell` again:

```
>>> from polls.models import Question, Choice

# Make sure our __str__() addition worked.
>>> Question.objects.all()
<QuerySet [<Question: What's up?>]>

# Django provides a rich database lookup API that's entirely driven by
# keyword arguments.
>>> Question.objects.filter(id=1)
<QuerySet [<Question: What's up?>]>
>>> Question.objects.filter(question_text__startswith='What')
<QuerySet [<Question: What's up?>]>

# Get the question that was published this year.
>>> from django.utils import timezone
>>> current_year = timezone.now().year
>>> Question.objects.get(pub_date__year=current_year)
<Question: What's up?>

# Request an ID that doesn't exist, this will raise an exception.
>>> Question.objects.get(id=2)
Traceback (most recent call last):
...
DoesNotExist: Question matching query does not exist.

# Lookup by a primary key is the most common case, so Django provides a
# shortcut for primary-key exact lookups.
# The following is identical to Question.objects.get(id=1).
>>> Question.objects.get(pk=1)
<Question: What's up?>

# Make sure our custom method worked.
>>> q = Question.objects.get(pk=1)
>>> q.was_published_recently()
True

# Give the Question a couple of Choices. The create call constructs a new
# Choice object, does the INSERT statement, adds the choice to the set
# of available choices and returns the new Choice object. Django creates
# a set to hold the "other side" of a ForeignKey relation
# (e.g. a question's choice) which can be accessed via the API.
>>> q = Question.objects.get(pk=1)

# Display any choices from the related object set -- none so far.
>>> q.choice_set.all()
<QuerySet []>

# Create three choices.
>>> q.choice_set.create(choice_text='Not much', votes=0)
<Choice: Not much>
>>> q.choice_set.create(choice_text='The sky', votes=0)
<Choice: The sky>
```

```

>>> c = q.choice_set.create(choice_text='Just hacking again', votes=0)

# Choice objects have API access to their related Question objects.
>>> c.question
<Question: What's up?>

# And vice versa: Question objects get access to Choice objects.
>>> q.choice_set.all()
<QuerySet [<Choice: Not much>, <Choice: The sky>, <Choice: Just hacking again>]>
>>> q.choice_set.count()
3

# The API automatically follows relationships as far as you need.
# Use double underscores to separate relationships.
# This works as many levels deep as you want; there's no limit.
# Find all Choices for any question whose pub_date is in this year
# (reusing the 'current_year' variable we created above).
>>> Choice.objects.filter(question__pub_date__year=current_year)
<QuerySet [<Choice: Not much>, <Choice: The sky>, <Choice: Just hacking again>]>

# Let's delete one of the choices. Use delete() for that.
>>> c = q.choice_set.filter(choice_text__startswith='Just hacking')
>>> c.delete()

```

For more information on model relations, see [Accessing related objects](#). For more on how to use double underscores to perform field lookups via the API, see [Field lookups](#). For full details on the database API, see our [Database API reference](#).

## 2.4.5 Introducing the Django Admin

### Philosophy

Generating admin sites for your staff or clients to add, change, and delete content is tedious work that doesn't require much creativity. For that reason, Django entirely automates creation of admin interfaces for models.

Django was written in a newsroom environment, with a very clear separation between “content publishers” and the “public” site. Site managers use the system to add news stories, events, sports scores, etc., and that content is displayed on the public site. Django solves the problem of creating a unified interface for site administrators to edit content.

The admin isn't intended to be used by site visitors. It's for site managers.

### Creating an admin user

First we'll need to create a user who can login to the admin site. Run the following command:

```
$ python manage.py createsuperuser
```

Enter your desired username and press enter.

```
Username: admin
```

You will then be prompted for your desired email address:

```
Email address: admin@example.com
```

The final step is to enter your password. You will be asked to enter your password twice, the second time as a confirmation of the first.

```
Password: *****  
Password (again): *****  
Superuser created successfully.
```

### Start the development server

The Django admin site is activated by default. Let's start the development server and explore it.

If the server is not running start it like so:

```
$ python manage.py runserver
```

Now, open a Web browser and go to “/admin/” on your local domain – e.g., <http://127.0.0.1:8000/admin/>. You should see the admin's login screen:

The screenshot shows the Django administration login interface. It features a dark blue header with the text "Django administration". Below the header, there are two input fields: "Username:" and "Password:". At the bottom center, there is a blue button labeled "Log in".

Since *translation* is turned on by default, the login screen may be displayed in your own language, depending on your browser's settings and if Django has a translation for this language.

### Enter the admin site

Now, try logging in with the superuser account you created in the previous step. You should see the Django admin index page:

## Django administration

WELCOME, ADMIN. [VIEW SITE](#) / [CHANGE PASSWORD](#) / [LOG OUT](#)

## Site administration

AUTHENTICATION AND AUTHORIZATION	
<a href="#">Groups</a>	<a href="#">+ Add</a> <a href="#">✎ Change</a>
<a href="#">Users</a>	<a href="#">+ Add</a> <a href="#">✎ Change</a>

**Recent Actions**

---

**My Actions**

None available

You should see a few types of editable content: groups and users. They are provided by `django.contrib.auth`, the authentication framework shipped by Django.

### Make the poll app modifiable in the admin

But where's our poll app? It's not displayed on the admin index page.

Just one thing to do: we need to tell the admin that `Question` objects have an admin interface. To do this, open the `polls/admin.py` file, and edit it to look like this:

```
polls/admin.py
from django.contrib import admin
from .models import Question
admin.site.register(Question)
```

### Explore the free admin functionality

Now that we've registered `Question`, Django knows that it should be displayed on the admin index page:

AUTHENTICATION AND AUTHORIZATION	
<a href="#">Groups</a>	<a href="#">+ Add</a> <a href="#">✎ Change</a>
<a href="#">Users</a>	<a href="#">+ Add</a> <a href="#">✎ Change</a>

**Recent Actions**

---

**My Actions**

None available

POLLS	
<a href="#">Questions</a>	<a href="#">+ Add</a> <a href="#">✎ Change</a>

Click "Questions". Now you're at the "change list" page for questions. This page displays all the questions in the database and lets you choose one to change it. There's the "What's up?" question we created earlier:

Home > Polls > Questions

Select question to change ADD QUESTION +

Action:   0 of 1 selected

QUESTION

What's up?

---

1 question

Click the “What’s up?” question to edit it:

Home > Polls > Questions > What's up?

Change question HISTORY

Question text:

---

Date published:

Date:  Today

Time:  Now

---

Things to note here:

- The form is automatically generated from the `Question` model.
- The different model field types (`DateTimeField`, `CharField`) correspond to the appropriate HTML input widget. Each type of field knows how to display itself in the Django admin.
- Each `DateTimeField` gets free JavaScript shortcuts. Dates get a “Today” shortcut and calendar popup, and times get a “Now” shortcut and a convenient popup that lists commonly entered times.

The bottom part of the page gives you a couple of options:

- Save – Saves changes and returns to the change-list page for this type of object.
- Save and continue editing – Saves changes and reloads the admin page for this object.
- Save and add another – Saves changes and loads a new, blank form for this type of object.
- Delete – Displays a delete confirmation page.

If the value of “Date published” doesn’t match the time when you created the question in [Tutorial 1](#), it probably means you forgot to set the correct value for the `TIME_ZONE` setting. Change it, reload the page and check that the correct value appears.

Change the “Date published” by clicking the “Today” and “Now” shortcuts. Then click “Save and continue editing.” Then click “History” in the upper right. You’ll see a page listing all changes made to this object via the Django admin, with the timestamp and username of the person who made the change:

Home › Polls › Questions › What's up? › History

Change history: What's up?

DATE/TIME	USER	ACTION
Sept. 6, 2015, 9:21 p.m.	elky	Changed pub_date.

When you're comfortable with the models API and have familiarized yourself with the admin site, read *part 3 of this tutorial* to learn about how to add more views to our polls app.

## 2.5 Writing your first Django app, part 3

This tutorial begins where *Tutorial 2* left off. We're continuing the Web-poll application and will focus on creating the public interface – “views.”

### 2.5.1 Overview

A view is a “type” of Web page in your Django application that generally serves a specific function and has a specific template. For example, in a blog application, you might have the following views:

- Blog homepage – displays the latest few entries.
- Entry “detail” page – permalink page for a single entry.
- Year-based archive page – displays all months with entries in the given year.
- Month-based archive page – displays all days with entries in the given month.
- Day-based archive page – displays all entries in the given day.
- Comment action – handles posting comments to a given entry.

In our poll application, we'll have the following four views:

- Question “index” page – displays the latest few questions.
- Question “detail” page – displays a question text, with no results but with a form to vote.
- Question “results” page – displays results for a particular question.
- Vote action – handles voting for a particular choice in a particular question.

In Django, web pages and other content are delivered by views. Each view is represented by a simple Python function (or method, in the case of class-based views). Django will choose a view by examining the URL that's requested (to be precise, the part of the URL after the domain name).

Now in your time on the web you may have come across such beauties as “ME2/Sites/dirmod.asp?sid=&type=gen&mod=Core+Pages&gid=A6CD4967199A42D9B65B1B”. You will be pleased to know that Django allows us much more elegant *URL patterns* than that.

A URL pattern is simply the general form of a URL - for example: `/newsarchive/<year>/<month>/`.

To get from a URL to a view, Django uses what are known as ‘URLconfs’. A URLconf maps URL patterns (described as regular expressions) to views.

This tutorial provides basic instruction in the use of URLconfs, and you can refer to *django.urls* for more information.

## 2.5.2 Writing more views

Now let's add a few more views to `polls/views.py`. These views are slightly different, because they take an argument:

```
polls/views.py

def detail(request, question_id):
    return HttpResponse("You're looking at question %s." % question_id)

def results(request, question_id):
    response = "You're looking at the results of question %s."
    return HttpResponse(response % question_id)

def vote(request, question_id):
    return HttpResponse("You're voting on question %s." % question_id)
```

Wire these new views into the `polls.urls` module by adding the following `url()` calls:

```
polls/urls.py

from django.conf.urls import url

from . import views

urlpatterns = [
    # ex: /polls/
    url(r'^$', views.index, name='index'),
    # ex: /polls/5/
    url(r'^(?P<question_id>[0-9]+)/$', views.detail, name='detail'),
    # ex: /polls/5/results/
    url(r'^(?P<question_id>[0-9]+)/results/$', views.results, name='results'),
    # ex: /polls/5/vote/
    url(r'^(?P<question_id>[0-9]+)/vote/$', views.vote, name='vote'),
]
```

Take a look in your browser, at `/polls/34/`. It'll run the `detail()` method and display whatever ID you provide in the URL. Try `/polls/34/results/` and `/polls/34/vote/` too – these will display the placeholder results and voting pages.

When somebody requests a page from your website – say, `/polls/34/`, Django will load the `mysite.urls` Python module because it's pointed to by the `ROOT_URLCONF` setting. It finds the variable named `urlpatterns` and traverses the regular expressions in order. After finding the match at `^polls/`, it strips off the matching text (`"polls/"`) and sends the remaining text – `"34/"` – to the `'polls.urls'` URLconf for further processing. There it matches `r'^(?P<question_id>[0-9]+)/$'`, resulting in a call to the `detail()` view like so:

```
detail(request=<HttpRequest object>, question_id='34')
```

The `question_id='34'` part comes from `(?P<question_id>[0-9]+)`. Using parentheses around a pattern “captures” the text matched by that pattern and sends it as an argument to the view function; `?P<question_id>` defines the name that will be used to identify the matched pattern; and `[0-9]+` is a regular expression to match a sequence of digits (i.e., a number).

Because the URL patterns are regular expressions, there really is no limit on what you can do with them. And there's no need to add URL cruft such as `.html` – unless you want to, in which case you can do something like this:

```
url(r'^polls/latest\.html$', views.index),
```

But, don't do that. It's silly.

### 2.5.3 Write views that actually do something

Each view is responsible for doing one of two things: returning an `HttpResponse` object containing the content for the requested page, or raising an exception such as `Http404`. The rest is up to you.

Your view can read records from a database, or not. It can use a template system such as Django’s – or a third-party Python template system – or not. It can generate a PDF file, output XML, create a ZIP file on the fly, anything you want, using whatever Python libraries you want.

All Django wants is that `HttpResponse`. Or an exception.

Because it’s convenient, let’s use Django’s own database API, which we covered in [Tutorial 2](#). Here’s one stab at a new `index()` view, which displays the latest 5 poll questions in the system, separated by commas, according to publication date:

```
polls/views.py

from django.http import HttpResponse

from .models import Question

def index(request):
    latest_question_list = Question.objects.order_by('-pub_date')[:5]
    output = ', '.join([q.question_text for q in latest_question_list])
    return HttpResponse(output)

# Leave the rest of the views (detail, results, vote) unchanged
```

There’s a problem here, though: the page’s design is hard-coded in the view. If you want to change the way the page looks, you’ll have to edit this Python code. So let’s use Django’s template system to separate the design from Python by creating a template that the view can use.

First, create a directory called `templates` in your `polls` directory. Django will look for templates in there.

Your project’s `TEMPLATES` setting describes how Django will load and render templates. The default settings file configures a `DjangoTemplates` backend whose `APP_DIRS` option is set to `True`. By convention `DjangoTemplates` looks for a “templates” subdirectory in each of the `INSTALLED_APPS`.

Within the `templates` directory you have just created, create another directory called `polls`, and within that create a file called `index.html`. In other words, your template should be at `polls/templates/polls/index.html`. Because of how the `app_directories` template loader works as described above, you can refer to this template within Django simply as `polls/index.html`.

---

#### Template namespacing

Now we *might* be able to get away with putting our templates directly in `polls/templates` (rather than creating another `polls` subdirectory), but it would actually be a bad idea. Django will choose the first template it finds whose name matches, and if you had a template with the same name in a *different* application, Django would be unable to distinguish between them. We need to be able to point Django at the right one, and the easiest way to ensure this is by *namespacing* them. That is, by putting those templates inside *another* directory named for the application itself.

---

Put the following code in that template:

```
polls/templates/polls/index.html

{% if latest_question_list %}
<ul>
  {% for question in latest_question_list %}
    <li><a href="/polls/{{ question.id }}/"/>{{ question.question_text }}</a></li>
```

```
        {% endfor %}
    </ul>
{% else %}
    <p>No polls are available.</p>
{% endif %}
```

Now let's update our index view in `polls/views.py` to use the template:

```
polls/views.py

from django.http import HttpResponseRedirect
from django.template import loader

from .models import Question

def index(request):
    latest_question_list = Question.objects.order_by('-pub_date')[:5]
    template = loader.get_template('polls/index.html')
    context = {
        'latest_question_list': latest_question_list,
    }
    return HttpResponseRedirect(template.render(context, request))
```

That code loads the template called `polls/index.html` and passes it a context. The context is a dictionary mapping template variable names to Python objects.

Load the page by pointing your browser at `"/polls/"`, and you should see a bulleted-list containing the “What’s up” question from *Tutorial 2*. The link points to the question’s detail page.

### A shortcut: `render()`

It's a very common idiom to load a template, fill a context and return an `HttpResponse` object with the result of the rendered template. Django provides a shortcut. Here's the full `index()` view, rewritten:

```
polls/views.py

from django.shortcuts import render

from .models import Question

def index(request):
    latest_question_list = Question.objects.order_by('-pub_date')[:5]
    context = {'latest_question_list': latest_question_list}
    return render(request, 'polls/index.html', context)
```

Note that once we've done this in all these views, we no longer need to import `loader` and `HttpResponse` (you'll want to keep `HttpResponse` if you still have the stub methods for `detail`, `results`, and `vote`).

The `render()` function takes the request object as its first argument, a template name as its second argument and a dictionary as its optional third argument. It returns an `HttpResponse` object of the given template rendered with the given context.

## 2.5.4 Raising a 404 error

Now, let's tackle the question detail view – the page that displays the question text for a given poll. Here's the view:

```
polls/views.py
```

```
from django.http import Http404
from django.shortcuts import render

from .models import Question
# ...
def detail(request, question_id):
    try:
        question = Question.objects.get(pk=question_id)
    except Question.DoesNotExist:
        raise Http404("Question does not exist")
    return render(request, 'polls/detail.html', {'question': question})
```

The new concept here: The view raises the `Http404` exception if a question with the requested ID doesn't exist.

We'll discuss what you could put in that `polls/detail.html` template a bit later, but if you'd like to quickly get the above example working, a file containing just:

```
polls/templates/polls/detail.html

{{ question }}
```

will get you started for now.

### A shortcut: `get_object_or_404()`

It's a very common idiom to use `get()` and raise `Http404` if the object doesn't exist. Django provides a shortcut. Here's the `detail()` view, rewritten:

```
polls/views.py

from django.shortcuts import get_object_or_404, render

from .models import Question
# ...
def detail(request, question_id):
    question = get_object_or_404(Question, pk=question_id)
    return render(request, 'polls/detail.html', {'question': question})
```

The `get_object_or_404()` function takes a Django model as its first argument and an arbitrary number of keyword arguments, which it passes to the `get()` function of the model's manager. It raises `Http404` if the object doesn't exist.

---

### Philosophy

Why do we use a helper function `get_object_or_404()` instead of automatically catching the `ObjectDoesNotExist` exceptions at a higher level, or having the model API raise `Http404` instead of `ObjectDoesNotExist`?

Because that would couple the model layer to the view layer. One of the foremost design goals of Django is to maintain loose coupling. Some controlled coupling is introduced in the `django.shortcuts` module.

---

There's also a `get_list_or_404()` function, which works just as `get_object_or_404()` – except using `filter()` instead of `get()`. It raises `Http404` if the list is empty.

## 2.5.5 Use the template system

Back to the `detail()` view for our poll application. Given the context variable `question`, here's what the `polls/detail.html` template might look like:

```
polls/templates/polls/detail.html
```

```
<h1>{{ question.question_text }}</h1>
<ul>
{% for choice in question.choice_set.all %}
    <li>{{ choice.choice_text }}</li>
{% endfor %}
</ul>
```

The template system uses dot-lookup syntax to access variable attributes. In the example of `{{ question.question_text }}`, first Django does a dictionary lookup on the object `question`. Failing that, it tries an attribute lookup – which works, in this case. If attribute lookup had failed, it would’ve tried a list-index lookup.

Method-calling happens in the `{% for %}` loop: `question.choice_set.all` is interpreted as the Python code `question.choice_set.all()`, which returns an iterable of `Choice` objects and is suitable for use in the `{% for %}` tag.

See the *template guide* for more about templates.

## 2.5.6 Removing hardcoded URLs in templates

Remember, when we wrote the link to a question in the `polls/index.html` template, the link was partially hardcoded like this:

```
<li><a href="/polls/{{ question.id }}/">{{ question.question_text }}</a></li>
```

The problem with this hardcoded, tightly-coupled approach is that it becomes challenging to change URLs on projects with a lot of templates. However, since you defined the name argument in the `url()` functions in the `polls.urls` module, you can remove a reliance on specific URL paths defined in your url configurations by using the `{% url %}` template tag:

```
<li><a href="{% url 'detail' question.id %}">{{ question.question_text }}</a></li>
```

The way this works is by looking up the URL definition as specified in the `polls.urls` module. You can see exactly where the URL name of ‘detail’ is defined below:

```
...
# the 'name' value as called by the {% url %} template tag
url(r'^(?P<question_id>[0-9]+)/$', views.detail, name='detail'),
...
```

If you want to change the URL of the polls detail view to something else, perhaps to something like `polls/specifics/12/` instead of doing it in the template (or templates) you would change it in `polls/urls.py`:

```
...
# added the word 'specifics'
url(r'^specifics/(?P<question_id>[0-9]+)/$', views.detail, name='detail'),
...
```

## 2.5.7 Namespacing URL names

The tutorial project has just one app, `polls`. In real Django projects, there might be five, ten, twenty apps or more. How does Django differentiate the URL names between them? For example, the `polls` app has a `detail` view, and so might an app on the same project that is for a blog. How does one make it so that Django knows which app view to create for a url when using the `{% url %}` template tag?

The answer is to add namespaces to your URLconf. In the `polls/urls.py` file, go ahead and add an `app_name` to set the application namespace:

```
polls/urls.py

from django.conf.urls import url

from . import views

app_name = 'polls'
urlpatterns = [
    url(r'^$', views.index, name='index'),
    url(r'^(?P<question_id>[0-9]+)/$', views.detail, name='detail'),
    url(r'^(?P<question_id>[0-9]+)/results/$', views.results, name='results'),
    url(r'^(?P<question_id>[0-9]+)/vote/$', views.vote, name='vote'),
]
```

Now change your `polls/index.html` template from:

```
polls/templates/polls/index.html

<li><a href="{% url 'detail' question.id %}">{{ question.question_text }}</a></li>
```

to point at the namespaced detail view:

```
polls/templates/polls/index.html

<li><a href="{% url 'polls:detail' question.id %}">{{ question.question_text }}</a></li>
```

When you're comfortable with writing views, read *part 4 of this tutorial* to learn about simple form processing and generic views.

## 2.6 Writing your first Django app, part 4

This tutorial begins where *Tutorial 3* left off. We're continuing the Web-poll application and will focus on simple form processing and cutting down our code.

### 2.6.1 Write a simple form

Let's update our poll detail template ("polls/detail.html") from the last tutorial, so that the template contains an HTML `<form>` element:

```
polls/templates/polls/detail.html

<h1>{{ question.question_text }}</h1>

{% if error_message %}<p><strong>{{ error_message }}</strong></p>{% endif %}

<form action="{% url 'polls:vote' question.id %}" method="post">
{% csrf_token %}
{% for choice in question.choice_set.all %}
    <input type="radio" name="choice" id="choice{{ forloop.counter }}" value="{{ choice.id }}" />
    <label for="choice{{ forloop.counter }}">{{ choice.choice_text }}</label><br />
{% endfor %}
<input type="submit" value="Vote" />
</form>
```

A quick rundown:

- The above template displays a radio button for each question choice. The value of each radio button is the associated question choice's ID. The name of each radio button is "choice". That means, when somebody selects one of the radio buttons and submits the form, it'll send the POST data `choice=#` where # is the ID of the selected choice. This is the basic concept of HTML forms.
- We set the form's action to `{% url 'polls:vote' question.id %}`, and we set `method="post"`. Using `method="post"` (as opposed to `method="get"`) is very important, because the act of submitting this form will alter data server-side. Whenever you create a form that alters data server-side, use `method="post"`. This tip isn't specific to Django; it's just good Web development practice.
- `forloop.counter` indicates how many times the `for` tag has gone through its loop
- Since we're creating a POST form (which can have the effect of modifying data), we need to worry about Cross Site Request Forgeries. Thankfully, you don't have to worry too hard, because Django comes with a very easy-to-use system for protecting against it. In short, all POST forms that are targeted at internal URLs should use the `{% csrf_token %}` template tag.

Now, let's create a Django view that handles the submitted data and does something with it. Remember, in [Tutorial 3](#), we created a URLconf for the polls application that includes this line:

```
polls/urls.py
```

```
url(r'^(?P<question_id>[0-9]+)/vote/$', views.vote, name='vote'),
```

We also created a dummy implementation of the `vote()` function. Let's create a real version. Add the following to `polls/views.py`:

```
polls/views.py
```

```
from django.shortcuts import get_object_or_404, render
from django.http import HttpResponseRedirect, HttpResponse
from django.urls import reverse

from .models import Choice, Question
# ...
def vote(request, question_id):
    question = get_object_or_404(Question, pk=question_id)
    try:
        selected_choice = question.choice_set.get(pk=request.POST['choice'])
    except (KeyError, Choice.DoesNotExist):
        # Redisplay the question voting form.
        return render(request, 'polls/detail.html', {
            'question': question,
            'error_message': "You didn't select a choice.",
        })
    else:
        selected_choice.votes += 1
        selected_choice.save()
        # Always return an HttpResponseRedirect after successfully dealing
        # with POST data. This prevents data from being posted twice if a
        # user hits the Back button.
        return HttpResponseRedirect(reverse('polls:results', args=(question.id,)))
```

This code includes a few things we haven't covered yet in this tutorial:

- `request.POST` is a dictionary-like object that lets you access submitted data by key name. In this case, `request.POST['choice']` returns the ID of the selected choice, as a string. `request.POST` values are always strings.

Note that Django also provides `request.GET` for accessing GET data in the same way – but we're explicitly using `request.POST` in our code, to ensure that data is only altered via a POST call.

- `request.POST['choice']` will raise `KeyError` if `choice` wasn't provided in POST data. The above code checks for `KeyError` and redisplay the question form with an error message if `choice` isn't given.
- After incrementing the choice count, the code returns an `HttpResponseRedirect` rather than a normal `HttpResponse`. `HttpResponseRedirect` takes a single argument: the URL to which the user will be redirected (see the following point for how we construct the URL in this case).

As the Python comment above points out, you should always return an `HttpResponseRedirect` after successfully dealing with POST data. This tip isn't specific to Django; it's just good Web development practice.

- We are using the `reverse()` function in the `HttpResponseRedirect` constructor in this example. This function helps avoid having to hardcode a URL in the view function. It is given the name of the view that we want to pass control to and the variable portion of the URL pattern that points to that view. In this case, using the URLconf we set up in *Tutorial 3*, this `reverse()` call will return a string like

```
'/polls/3/results/'
```

where the 3 is the value of `question.id`. This redirected URL will then call the 'results' view to display the final page.

As mentioned in *Tutorial 3*, `request` is an `HttpRequest` object. For more on `HttpRequest` objects, see the *request and response documentation*.

After somebody votes in a question, the `vote()` view redirects to the results page for the question. Let's write that view:

```
polls/views.py
```

```
from django.shortcuts import get_object_or_404, render
```

```
def results(request, question_id):
    question = get_object_or_404(Question, pk=question_id)
    return render(request, 'polls/results.html', {'question': question})
```

This is almost exactly the same as the `detail()` view from *Tutorial 3*. The only difference is the template name. We'll fix this redundancy later.

Now, create a `polls/results.html` template:

```
polls/templates/polls/results.html
```

```
<h1>{{ question.question_text }}</h1>
```

```
<ul>
```

```
{% for choice in question.choice_set.all %}
```

```
  <li>{{ choice.choice_text }} -- {{ choice.votes }} vote{{ choice.votes|pluralize }}</li>
```

```
{% endfor %}
```

```
</ul>
```

```
<a href="{% url 'polls:detail' question.id %}">Vote again?</a>
```

Now, go to `/polls/1/` in your browser and vote in the question. You should see a results page that gets updated each time you vote. If you submit the form without having chosen a choice, you should see the error message.

---

**Note:** The code for our `vote()` view does have a small problem. It first gets the `selected_choice` object from the database, then computes the new value of `votes`, and then saves it back to the database. If two users of your website try to vote at *exactly the same time*, this might go wrong: The same value, let's say 42, will be retrieved for `votes`. Then, for both users the new value of 43 is computed and saved, but 44 would be the expected value.

This is called a *race condition*. If you are interested, you can read *Avoiding race conditions using F()* to learn how you can solve this issue.

---

## 2.6.2 Use generic views: Less code is better

The `detail()` (from *Tutorial 3*) and `results()` views are very simple – and, as mentioned above, redundant. The `index()` view, which displays a list of polls, is similar.

These views represent a common case of basic Web development: getting data from the database according to a parameter passed in the URL, loading a template and returning the rendered template. Because this is so common, Django provides a shortcut, called the “generic views” system.

Generic views abstract common patterns to the point where you don’t even need to write Python code to write an app.

Let’s convert our poll app to use the generic views system, so we can delete a bunch of our own code. We’ll just have to take a few steps to make the conversion. We will:

1. Convert the URLconf.
2. Delete some of the old, unneeded views.
3. Introduce new views based on Django’s generic views.

Read on for details.

---

### Why the code-shuffle?

Generally, when writing a Django app, you’ll evaluate whether generic views are a good fit for your problem, and you’ll use them from the beginning, rather than refactoring your code halfway through. But this tutorial intentionally has focused on writing the views “the hard way” until now, to focus on core concepts.

You should know basic math before you start using a calculator.

---

### Amend URLconf

First, open the `polls/urls.py` URLconf and change it like so:

```
polls/urls.py
from django.conf.urls import url

from . import views

app_name = 'polls'
urlpatterns = [
    url(r'^$', views.IndexView.as_view(), name='index'),
    url(r'^(?P<pk>[0-9]+)/$', views.DetailView.as_view(), name='detail'),
    url(r'^(?P<pk>[0-9]+)/results/$', views.ResultsView.as_view(), name='results'),
    url(r'^(?P<question_id>[0-9]+)/vote/$', views.vote, name='vote'),
]
```

Note that the name of the matched pattern in the regexes of the second and third patterns has changed from `<question_id>` to `<pk>`.

## Amend views

Next, we're going to remove our old `index`, `detail`, and `results` views and use Django's generic views instead. To do so, open the `polls/views.py` file and change it like so:

```
polls/views.py

from django.shortcuts import get_object_or_404, render
from django.http import HttpResponseRedirect
from django.urls import reverse
from django.views import generic

from .models import Choice, Question

class IndexView(generic.ListView):
    template_name = 'polls/index.html'
    context_object_name = 'latest_question_list'

    def get_queryset(self):
        """Return the last five published questions."""
        return Question.objects.order_by('-pub_date')[:5]

class DetailView(generic.DetailView):
    model = Question
    template_name = 'polls/detail.html'

class ResultsView(generic.DetailView):
    model = Question
    template_name = 'polls/results.html'

def vote(request, question_id):
    ... # same as above, no changes needed.
```

We're using two generic views here: `ListView` and `DetailView`. Respectively, those two views abstract the concepts of “display a list of objects” and “display a detail page for a particular type of object.”

- Each generic view needs to know what model it will be acting upon. This is provided using the `model` attribute.
- The `DetailView` generic view expects the primary key value captured from the URL to be called “pk”, so we've changed `question_id` to `pk` for the generic views.

By default, the `DetailView` generic view uses a template called `<app name>/<model name>_detail.html`. In our case, it would use the template `"polls/question_detail.html"`. The `template_name` attribute is used to tell Django to use a specific template name instead of the autogenerated default template name. We also specify the `template_name` for the `results` list view – this ensures that the `results` view and the `detail` view have a different appearance when rendered, even though they're both a `DetailView` behind the scenes.

Similarly, the `ListView` generic view uses a default template called `<app name>/<model name>_list.html`; we use `template_name` to tell `ListView` to use our existing `"polls/index.html"` template.

In previous parts of the tutorial, the templates have been provided with a context that contains the `question` and `latest_question_list` context variables. For `DetailView` the `question` variable is provided automatically – since we're using a Django model (`Question`), Django is able to determine an appropriate name for the context variable. However, for `ListView`, the automatically generated context variable is `question_list`. To override this we provide the `context_object_name` attribute, specifying that we want to

use `latest_question_list` instead. As an alternative approach, you could change your templates to match the new default context variables – but it’s a lot easier to just tell Django to use the variable you want.

Run the server, and use your new polling app based on generic views.

For full details on generic views, see the [generic views documentation](#).

When you’re comfortable with forms and generic views, read [part 5 of this tutorial](#) to learn about testing our polls app.

## 2.7 Writing your first Django app, part 5

This tutorial begins where [Tutorial 4](#) left off. We’ve built a Web-poll application, and we’ll now create some automated tests for it.

### 2.7.1 Introducing automated testing

#### What are automated tests?

Tests are simple routines that check the operation of your code.

Testing operates at different levels. Some tests might apply to a tiny detail (*does a particular model method return values as expected?*) while others examine the overall operation of the software (*does a sequence of user inputs on the site produce the desired result?*). That’s no different from the kind of testing you did earlier in [Tutorial 2](#), using the `shell` to examine the behavior of a method, or running the application and entering data to check how it behaves.

What’s different in *automated* tests is that the testing work is done for you by the system. You create a set of tests once, and then as you make changes to your app, you can check that your code still works as you originally intended, without having to perform time consuming manual testing.

#### Why you need to create tests

So why create tests, and why now?

You may feel that you have quite enough on your plate just learning Python/Django, and having yet another thing to learn and do may seem overwhelming and perhaps unnecessary. After all, our polls application is working quite happily now; going through the trouble of creating automated tests is not going to make it work any better. If creating the polls application is the last bit of Django programming you will ever do, then true, you don’t need to know how to create automated tests. But, if that’s not the case, now is an excellent time to learn.

#### Tests will save you time

Up to a certain point, ‘checking that it seems to work’ will be a satisfactory test. In a more sophisticated application, you might have dozens of complex interactions between components.

A change in any of those components could have unexpected consequences on the application’s behavior. Checking that it still ‘seems to work’ could mean running through your code’s functionality with twenty different variations of your test data just to make sure you haven’t broken something - not a good use of your time.

That’s especially true when automated tests could do this for you in seconds. If something’s gone wrong, tests will also assist in identifying the code that’s causing the unexpected behavior.

Sometimes it may seem a chore to tear yourself away from your productive, creative programming work to face the unglamorous and unexciting business of writing tests, particularly when you know your code is working properly.

However, the task of writing tests is a lot more fulfilling than spending hours testing your application manually or trying to identify the cause of a newly-introduced problem.

### Tests don't just identify problems, they prevent them

It's a mistake to think of tests merely as a negative aspect of development.

Without tests, the purpose or intended behavior of an application might be rather opaque. Even when it's your own code, you will sometimes find yourself poking around in it trying to find out what exactly it's doing.

Tests change that; they light up your code from the inside, and when something goes wrong, they focus light on the part that has gone wrong - *even if you hadn't even realized it had gone wrong*.

### Tests make your code more attractive

You might have created a brilliant piece of software, but you will find that many other developers will simply refuse to look at it because it lacks tests; without tests, they won't trust it. Jacob Kaplan-Moss, one of Django's original developers, says "Code without tests is broken by design."

That other developers want to see tests in your software before they take it seriously is yet another reason for you to start writing tests.

### Tests help teams work together

The previous points are written from the point of view of a single developer maintaining an application. Complex applications will be maintained by teams. Tests guarantee that colleagues don't inadvertently break your code (and that you don't break theirs without knowing). If you want to make a living as a Django programmer, you must be good at writing tests!

## 2.7.2 Basic testing strategies

There are many ways to approach writing tests.

Some programmers follow a discipline called "[test-driven development](#)"; they actually write their tests before they write their code. This might seem counter-intuitive, but in fact it's similar to what most people will often do anyway: they describe a problem, then create some code to solve it. Test-driven development simply formalizes the problem in a Python test case.

More often, a newcomer to testing will create some code and later decide that it should have some tests. Perhaps it would have been better to write some tests earlier, but it's never too late to get started.

Sometimes it's difficult to figure out where to get started with writing tests. If you have written several thousand lines of Python, choosing something to test might not be easy. In such a case, it's fruitful to write your first test the next time you make a change, either when you add a new feature or fix a bug.

So let's do that right away.

### 2.7.3 Writing our first test

#### We identify a bug

Fortunately, there's a little bug in the `polls` application for us to fix right away: the `Question.was_published_recently()` method returns `True` if the `Question` was published within the last day (which

is correct) but also if the `Question`'s `pub_date` field is in the future (which certainly isn't).

To check if the bug really exists, using the Admin create a question whose date lies in the future and check the method using the *shell*:

```
>>> import datetime
>>> from django.utils import timezone
>>> from polls.models import Question
>>> # create a Question instance with pub_date 30 days in the future
>>> future_question = Question(pub_date=timezone.now() + datetime.timedelta(days=30))
>>> # was it published recently?
>>> future_question.was_published_recently()
True
```

Since things in the future are not 'recent', this is clearly wrong.

### Create a test to expose the bug

What we've just done in the *shell* to test for the problem is exactly what we can do in an automated test, so let's turn that into an automated test.

A conventional place for an application's tests is in the application's `tests.py` file; the testing system will automatically find tests in any file whose name begins with `test`.

Put the following in the `tests.py` file in the `polls` application:

```
polls/tests.py

import datetime

from django.utils import timezone
from django.test import TestCase

from .models import Question

class QuestionMethodTests(TestCase):

    def test_was_published_recently_with_future_question(self):
        """
        was_published_recently() should return False for questions whose
        pub_date is in the future.
        """
        time = timezone.now() + datetime.timedelta(days=30)
        future_question = Question(pub_date=time)
        self.assertIs(future_question.was_published_recently(), False)
```

What we have done here is created a `django.test.TestCase` subclass with a method that creates a `Question` instance with a `pub_date` in the future. We then check the output of `was_published_recently()` - which *ought* to be `False`.

### Running tests

In the terminal, we can run our test:

```
$ python manage.py test polls
```

and you'll see something like:

```

Creating test database for alias 'default'...
F
=====
FAIL: test_was_published_recently_with_future_question (polls.tests.
↳QuestionMethodTests)
-----
Traceback (most recent call last):
  File "/path/to/mysite/polls/tests.py", line 16, in test_was_published_recently_with_
↳future_question
    self.assertIs(future_question.was_published_recently(), False)
AssertionError: True is not False
-----
Ran 1 test in 0.001s

FAILED (failures=1)
Destroying test database for alias 'default'...

```

What happened is this:

- `python manage.py test polls` looked for tests in the `polls` application
- it found a subclass of the `django.test.TestCase` class
- it created a special database for the purpose of testing
- it looked for test methods - ones whose names begin with `test`
- in `test_was_published_recently_with_future_question` it created a `Question` instance whose `pub_date` field is 30 days in the future
- ... and using the `assertIs()` method, it discovered that its `was_published_recently()` returns `True`, though we wanted it to return `False`

The test informs us which test failed and even the line on which the failure occurred.

## Fixing the bug

We already know what the problem is: `Question.was_published_recently()` should return `False` if its `pub_date` is in the future. Amend the method in `models.py`, so that it will only return `True` if the date is also in the past:

```
polls/models.py
```

```

def was_published_recently(self):
    now = timezone.now()
    return now - datetime.timedelta(days=1) <= self.pub_date <= now

```

and run the test again:

```

Creating test database for alias 'default'...
.
-----
Ran 1 test in 0.001s

OK
Destroying test database for alias 'default'...

```

After identifying a bug, we wrote a test that exposes it and corrected the bug in the code so our test passes.

Many other things might go wrong with our application in the future, but we can be sure that we won't inadvertently reintroduce this bug, because simply running the test will warn us immediately. We can consider this little portion of the application pinned down safely forever.

## More comprehensive tests

While we're here, we can further pin down the `was_published_recently()` method; in fact, it would be positively embarrassing if in fixing one bug we had introduced another.

Add two more test methods to the same class, to test the behavior of the method more comprehensively:

```
polls/tests.py

def test_was_published_recently_with_old_question(self):
    """
    was_published_recently() should return False for questions whose
    pub_date is older than 1 day.
    """
    time = timezone.now() - datetime.timedelta(days=30)
    old_question = Question(pub_date=time)
    self.assertIs(old_question.was_published_recently(), False)

def test_was_published_recently_with_recent_question(self):
    """
    was_published_recently() should return True for questions whose
    pub_date is within the last day.
    """
    time = timezone.now() - datetime.timedelta(hours=1)
    recent_question = Question(pub_date=time)
    self.assertIs(recent_question.was_published_recently(), True)
```

And now we have three tests that confirm that `Question.was_published_recently()` returns sensible values for past, recent, and future questions.

Again, `polls` is a simple application, but however complex it grows in the future and whatever other code it interacts with, we now have some guarantee that the method we have written tests for will behave in expected ways.

## 2.7.4 Test a view

The `polls` application is fairly indiscriminating: it will publish any question, including ones whose `pub_date` field lies in the future. We should improve this. Setting a `pub_date` in the future should mean that the `Question` is published at that moment, but invisible until then.

### A test for a view

When we fixed the bug above, we wrote the test first and then the code to fix it. In fact that was a simple example of test-driven development, but it doesn't really matter in which order we do the work.

In our first test, we focused closely on the internal behavior of the code. For this test, we want to check its behavior as it would be experienced by a user through a web browser.

Before we try to fix anything, let's have a look at the tools at our disposal.

```
    """Return the last five published questions."""
    return Question.objects.order_by('-pub_date')[:5]
```

We need to amend the `get_queryset()` method and change it so that it also checks the date by comparing it with `timezone.now()`. First we need to add an import:

```
polls/views.py
```

```
from django.utils import timezone
```

and then we must amend the `get_queryset` method like so:

```
polls/views.py
```

```
def get_queryset(self):
    """
    Return the last five published questions (not including those set to be
    published in the future).
    """
    return Question.objects.filter(
        pub_date__lte=timezone.now()
    ).order_by('-pub_date')[:5]
```

`Question.objects.filter(pub_date__lte=timezone.now())` returns a queryset containing Questions whose `pub_date` is less than or equal to - that is, earlier than or equal to - `timezone.now`.

## Testing our new view

Now you can satisfy yourself that this behaves as expected by firing up the runserver, loading the site in your browser, creating Questions with dates in the past and future, and checking that only those that have been published are listed. You don't want to have to do that *every single time you make any change that might affect this* - so let's also create a test, based on our *shell* session above.

Add the following to `polls/tests.py`:

```
polls/tests.py
```

```
from django.urls import reverse
```

and we'll create a shortcut function to create questions as well as a new test class:

```
polls/tests.py
```

```
def create_question(question_text, days):
    """
    Creates a question with the given `question_text` and published the
    given number of `days` offset to now (negative for questions published
    in the past, positive for questions that have yet to be published).
    """
    time = timezone.now() + datetime.timedelta(days=days)
    return Question.objects.create(question_text=question_text, pub_date=time)
```

```
class QuestionViewTests(TestCase):
    def test_index_view_with_no_questions(self):
        """
        If no questions exist, an appropriate message should be displayed.
        """
        response = self.client.get(reverse('polls:index'))
        self.assertEqual(response.status_code, 200)
        self.assertContains(response, "No polls are available.")
        self.assertQuerysetEqual(response.context['latest_question_list'], [])
```

```

def test_index_view_with_a_past_question(self):
    """
    Questions with a pub_date in the past should be displayed on the
    index page.
    """
    create_question(question_text="Past question.", days=-30)
    response = self.client.get(reverse('polls:index'))
    self.assertEqual(
        response.context['latest_question_list'],
        ['<Question: Past question.>']
    )

def test_index_view_with_a_future_question(self):
    """
    Questions with a pub_date in the future should not be displayed on
    the index page.
    """
    create_question(question_text="Future question.", days=30)
    response = self.client.get(reverse('polls:index'))
    self.assertContains(response, "No polls are available.")
    self.assertEqual(response.context['latest_question_list'], [])

def test_index_view_with_future_question_and_past_question(self):
    """
    Even if both past and future questions exist, only past questions
    should be displayed.
    """
    create_question(question_text="Past question.", days=-30)
    create_question(question_text="Future question.", days=30)
    response = self.client.get(reverse('polls:index'))
    self.assertEqual(
        response.context['latest_question_list'],
        ['<Question: Past question.>']
    )

def test_index_view_with_two_past_questions(self):
    """
    The questions index page may display multiple questions.
    """
    create_question(question_text="Past question 1.", days=-30)
    create_question(question_text="Past question 2.", days=-5)
    response = self.client.get(reverse('polls:index'))
    self.assertEqual(
        response.context['latest_question_list'],
        ['<Question: Past question 2.>', '<Question: Past question 1.>']
    )

```

Let's look at some of these more closely.

First is a question shortcut function, `create_question`, to take some repetition out of the process of creating questions.

`test_index_view_with_no_questions` doesn't create any questions, but checks the message: "No polls are available." and verifies the `latest_question_list` is empty. Note that the `django.test.TestCase` class provides some additional assertion methods. In these examples, we use `assertContains()` and `assertQuerysetEqual()`.

In `test_index_view_with_a_past_question`, we create a question and verify that it appears in the list.

In `test_index_view_with_a_future_question`, we create a question with a `pub_date` in the future. The database is reset for each test method, so the first question is no longer there, and so again the index shouldn't have any questions in it.

And so on. In effect, we are using the tests to tell a story of admin input and user experience on the site, and checking that at every state and for every new change in the state of the system, the expected results are published.

## Testing the `DetailView`

What we have works well; however, even though future questions don't appear in the *index*, users can still reach them if they know or guess the right URL. So we need to add a similar constraint to `DetailView`:

```
polls/views.py

class DetailView(generic.DetailView):
    ...
    def get_queryset(self):
        """
        Excludes any questions that aren't published yet.
        """
        return Question.objects.filter(pub_date__lte=timezone.now())
```

And of course, we will add some tests, to check that a `Question` whose `pub_date` is in the past can be displayed, and that one with a `pub_date` in the future is not:

```
polls/tests.py

class QuestionIndexDetailTests(TestCase):
    def test_detail_view_with_a_future_question(self):
        """
        The detail view of a question with a pub_date in the future should
        return a 404 not found.
        """
        future_question = create_question(question_text='Future question.', days=5)
        url = reverse('polls:detail', args=(future_question.id,))
        response = self.client.get(url)
        self.assertEqual(response.status_code, 404)

    def test_detail_view_with_a_past_question(self):
        """
        The detail view of a question with a pub_date in the past should
        display the question's text.
        """
        past_question = create_question(question_text='Past Question.', days=-5)
        url = reverse('polls:detail', args=(past_question.id,))
        response = self.client.get(url)
        self.assertContains(response, past_question.question_text)
```

## Ideas for more tests

We ought to add a similar `get_queryset` method to `ResultsView` and create a new test class for that view. It'll be very similar to what we have just created; in fact there will be a lot of repetition.

We could also improve our application in other ways, adding tests along the way. For example, it's silly that `Questions` can be published on the site that have no `Choices`. So, our views could check for this, and exclude such `Questions`. Our tests would create a `Question` without `Choices` and then test that it's not published, as well as create a similar `Question` *with* `Choices`, and test that it *is* published.

Perhaps logged-in admin users should be allowed to see unpublished `Questions`, but not ordinary visitors. Again: whatever needs to be added to the software to accomplish this should be accompanied by a test, whether you write the test first and then make the code pass the test, or work out the logic in your code first and then write a test to prove it.

At a certain point you are bound to look at your tests and wonder whether your code is suffering from test bloat, which brings us to:

### 2.7.5 When testing, more is better

It might seem that our tests are growing out of control. At this rate there will soon be more code in our tests than in our application, and the repetition is unaesthetic, compared to the elegant conciseness of the rest of our code.

**It doesn't matter.** Let them grow. For the most part, you can write a test once and then forget about it. It will continue performing its useful function as you continue to develop your program.

Sometimes tests will need to be updated. Suppose that we amend our views so that only `Questions` with `Choices` are published. In that case, many of our existing tests will fail - *telling us exactly which tests need to be amended to bring them up to date*, so to that extent tests help look after themselves.

At worst, as you continue developing, you might find that you have some tests that are now redundant. Even that's not a problem; in testing redundancy is a *good* thing.

As long as your tests are sensibly arranged, they won't become unmanageable. Good rules-of-thumb include having:

- a separate `TestClass` for each model or view
- a separate test method for each set of conditions you want to test
- test method names that describe their function

### 2.7.6 Further testing

This tutorial only introduces some of the basics of testing. There's a great deal more you can do, and a number of very useful tools at your disposal to achieve some very clever things.

For example, while our tests here have covered some of the internal logic of a model and the way our views publish information, you can use an "in-browser" framework such as [Selenium](#) to test the way your HTML actually renders in a browser. These tools allow you to check not just the behavior of your Django code, but also, for example, of your JavaScript. It's quite something to see the tests launch a browser, and start interacting with your site, as if a human being were driving it! Django includes `LiveServerTestCase` to facilitate integration with tools like Selenium.

If you have a complex application, you may want to run tests automatically with every commit for the purposes of [continuous integration](#), so that quality control is itself - at least partially - automated.

A good way to spot untested parts of your application is to check code coverage. This also helps identify fragile or even dead code. If you can't test a piece of code, it usually means that code should be refactored or removed. Coverage will help to identify dead code. See [Integration with coverage.py](#) for details.

[Testing in Django](#) has comprehensive information about testing.

### 2.7.7 What's next?

For full details on testing, see [Testing in Django](#).

When you're comfortable with testing Django views, read [part 6 of this tutorial](#) to learn about static files management.

## 2.8 Writing your first Django app, part 6

This tutorial begins where *Tutorial 5* left off. We’ve built a tested Web-poll application, and we’ll now add a stylesheet and an image.

Aside from the HTML generated by the server, web applications generally need to serve additional files — such as images, JavaScript, or CSS — necessary to render the complete web page. In Django, we refer to these files as “static files”.

For small projects, this isn’t a big deal, because you can just keep the static files somewhere your web server can find it. However, in bigger projects – especially those comprised of multiple apps – dealing with the multiple sets of static files provided by each application starts to get tricky.

That’s what `django.contrib.staticfiles` is for: it collects static files from each of your applications (and any other places you specify) into a single location that can easily be served in production.

### 2.8.1 Customize your *app’s* look and feel

First, create a directory called `static` in your `polls` directory. Django will look for static files there, similarly to how Django finds templates inside `polls/templates/`.

Django’s `STATICFILES_FINDERS` setting contains a list of finders that know how to discover static files from various sources. One of the defaults is `AppDirectoriesFinder` which looks for a “static” subdirectory in each of the `INSTALLED_APPS`, like the one in `polls` we just created. The admin site uses the same directory structure for its static files.

Within the `static` directory you have just created, create another directory called `polls` and within that create a file called `style.css`. In other words, your stylesheet should be at `polls/static/polls/style.css`. Because of how the `AppDirectoriesFinder` staticfile finder works, you can refer to this static file in Django simply as `polls/style.css`, similar to how you reference the path for templates.

---

#### Static file namespacing

Just like templates, we *might* be able to get away with putting our static files directly in `polls/static` (rather than creating another `polls` subdirectory), but it would actually be a bad idea. Django will choose the first static file it finds whose name matches, and if you had a static file with the same name in a *different* application, Django would be unable to distinguish between them. We need to be able to point Django at the right one, and the easiest way to ensure this is by *namespacing* them. That is, by putting those static files inside *another* directory named for the application itself.

---

Put the following code in that stylesheet (`polls/static/polls/style.css`):

```
polls/static/polls/style.css

li a {
    color: green;
}
```

Next, add the following at the top of `polls/templates/polls/index.html`:

```
polls/templates/polls/index.html

{% load static %}

<link rel="stylesheet" type="text/css" href="{% static 'polls/style.css' %}" />
```

The `{% static %}` template tag generates the absolute URL of static files.

That's all you need to do for development. Reload `http://localhost:8000/polls/` and you should see that the question links are green (Django style!) which means that your stylesheet was properly loaded.

## 2.8.2 Adding a background-image

Next, we'll create a subdirectory for images. Create an `images` subdirectory in the `polls/static/polls/` directory. Inside this directory, put an image called `background.gif`. In other words, put your image in `polls/static/polls/images/background.gif`.

Then, add to your stylesheet (`polls/static/polls/style.css`):

```
polls/static/polls/style.css
body {
    background: white url("images/background.gif") no-repeat right bottom;
}
```

Reload `http://localhost:8000/polls/` and you should see the background loaded in the bottom right of the screen.

**Warning:** Of course the `{% static %}` template tag is not available for use in static files like your stylesheet which aren't generated by Django. You should always use **relative paths** to link your static files between each other, because then you can change `STATIC_URL` (used by the `static` template tag to generate its URLs) without having to modify a bunch of paths in your static files as well.

These are the **basics**. For more details on settings and other bits included with the framework see [the static files howto](#) and [the staticfiles reference](#). [Deploying static files](#) discusses how to use static files on a real server.

When you're comfortable with the static files, read [part 7 of this tutorial](#) to learn how to customize Django's automatically-generated admin site.

## 2.9 Writing your first Django app, part 7

This tutorial begins where [Tutorial 6](#) left off. We're continuing the Web-poll application and will focus on customizing Django's automatically-generated admin site that we first explored in [Tutorial 2](#).

### 2.9.1 Customize the admin form

By registering the `Question` model with `admin.site.register(Question)`, Django was able to construct a default form representation. Often, you'll want to customize how the admin form looks and works. You'll do this by telling Django the options you want when you register the object.

Let's see how this works by reordering the fields on the edit form. Replace the `admin.site.register(Question)` line with:

```
polls/admin.py
from django.contrib import admin

from .models import Question

class QuestionAdmin(admin.ModelAdmin):
    fields = ['pub_date', 'question_text']
```

```
admin.site.register(Question, QuestionAdmin)
```

You'll follow this pattern – create a model admin class, then pass it as the second argument to `admin.site.register()` – any time you need to change the admin options for a model.

This particular change above makes the “Publication date” come before the “Question” field:

Home > Polls > Questions > What's up?

## Change question

Date published:

Date:  Today |   
Time:  Now | 

Question text:

This isn't impressive with only two fields, but for admin forms with dozens of fields, choosing an intuitive order is an important usability detail.

And speaking of forms with dozens of fields, you might want to split the form up into fieldsets:

```
polls/admin.py
```

```
from django.contrib import admin
```

```
from .models import Question
```

```
class QuestionAdmin(admin.ModelAdmin):  
    fieldsets = [  
        (None, {'fields': ['question_text']}),  
        ('Date information', {'fields': ['pub_date']}),  
    ]
```

```
admin.site.register(Question, QuestionAdmin)
```

The first element of each tuple in `fieldsets` is the title of the fieldset. Here's what our form looks like now:

Home > Polls > Questions > What's up?

## Change question

Question text:

### Date information

Date published:

Date:  Today | 

Time:  Now | 

## 2.9.2 Adding related objects

OK, we have our Question admin page, but a Question has multiple Choices, and the admin page doesn't display choices.

Yet.

There are two ways to solve this problem. The first is to register Choice with the admin just as we did with Question. That's easy:

```
polls/admin.py
from django.contrib import admin

from .models import Choice, Question
# ...
admin.site.register(Choice)
```

Now "Choices" is an available option in the Django admin. The "Add choice" form looks like this:

Home > Polls > Choices > Add choice

## Add choice

**Question:**    

---

**Choice text:**

---

**Votes:**

In that form, the “Question” field is a select box containing every question in the database. Django knows that a *ForeignKey* should be represented in the admin as a `<select>` box. In our case, only one question exists at this point.

Also note the “Add Another” link next to “Question.” Every object with a *ForeignKey* relationship to another gets this for free. When you click “Add Another”, you’ll get a popup window with the “Add question” form. If you add a question in that window and click “Save”, Django will save the question to the database and dynamically add it as the selected choice on the “Add choice” form you’re looking at.

But, really, this is an inefficient way of adding *Choice* objects to the system. It’d be better if you could add a bunch of *Choices* directly when you create the *Question* object. Let’s make that happen.

Remove the `register()` call for the *Choice* model. Then, edit the *Question* registration code to read:

```
polls/admin.py
from django.contrib import admin

from .models import Choice, Question

class ChoiceInline(admin.StackedInline):
    model = Choice
    extra = 3

class QuestionAdmin(admin.ModelAdmin):
    fieldsets = [
        (None, {'fields': ['question_text']}),
        ('Date information', {'fields': ['pub_date'], 'classes': ['collapse']}),
    ]
    inlines = [ChoiceInline]

admin.site.register(Question, QuestionAdmin)
```

This tells Django: “Choice objects are edited on the *Question* admin page. By default, provide enough fields for 3 choices.”

Load the “Add question” page to see how that looks:

Home > Polls > Questions > Add question

### Add question

**Question text:**

---

Date information (Hide)

**Date published:** Date:  Today   
Time:  Now 

CHOICES

**Choice: #1**

**Choice text:**

**Votes:**

---

**Choice: #2**

**Choice text:**

**Votes:**

---

**Choice: #3**

**Choice text:**

**Votes:**

[+ Add another Choice](#)

It works like this: There are three slots for related Choices – as specified by `extra` – and each time you come back to the “Change” page for an already-created object, you get another three extra slots.

At the end of the three current slots you will find an “Add another Choice” link. If you click on it, a new slot will be added. If you want to remove the added slot, you can click on the X to the top right of the added slot. Note that you can’t remove the original three slots. This image shows an added slot:

CHOICES	
Choice: #1	
Choice text:	<input type="text"/>
Votes:	<input type="text" value="0"/>
Choice: #2	
Choice text:	<input type="text"/>
Votes:	<input type="text" value="0"/>
Choice: #3	
Choice text:	<input type="text"/>
Votes:	<input type="text" value="0"/>
Choice: #4	
Choice text:	<input type="text"/>
Votes:	<input type="text" value="0"/>
<a href="#">+ Add another Choice</a>	

One small problem, though. It takes a lot of screen space to display all the fields for entering related `Choice` objects. For that reason, Django offers a tabular way of displaying inline related objects; you just need to change the `ChoiceInline` declaration to read:

```
polls/admin.py
```

```
class ChoiceInline(admin.TabularInline):
    # ...
```

With that `TabularInline` (instead of `StackedInline`), the related objects are displayed in a more compact, table-based format:

CHOICES		
CHOICE TEXT	VOTES	DELETE?
<input type="text"/>	<input type="text" value="0"/>	
<input type="text"/>	<input type="text" value="0"/>	
<input type="text"/>	<input type="text" value="0"/>	
<a href="#">+ Add another Choice</a>		
<input type="button" value="Save and add another"/> <input type="button" value="Save and continue editing"/> <input type="button" value="SAVE"/>		

Note that there is an extra “Delete?” column that allows removing rows added using the “Add Another Choice” button and rows that have already been saved.

### 2.9.3 Customize the admin change list

Now that the Question admin page is looking good, let's make some tweaks to the “change list” page – the one that displays all the questions in the system.

Here's what it looks like at this point:

By default, Django displays the `str()` of each object. But sometimes it'd be more helpful if we could display individual fields. To do that, use the `list_display` admin option, which is a tuple of field names to display, as columns, on the change list page for the object:

```
polls/admin.py
```

```
class QuestionAdmin(admin.ModelAdmin):
    # ...
    list_display = ('question_text', 'pub_date')
```

Just for good measure, let's also include the `was_published_recently()` method from *Tutorial 2*:

```
polls/admin.py
```

```
class QuestionAdmin(admin.ModelAdmin):
    # ...
    list_display = ('question_text', 'pub_date', 'was_published_recently')
```

Now the question change list page looks like this:

You can click on the column headers to sort by those values – except in the case of the `was_published_recently` header, because sorting by the output of an arbitrary method is not supported. Also note that the column header for `was_published_recently` is, by default, the name of the method (with underscores replaced with spaces), and that each line contains the string representation of the output.

You can improve that by giving that method (in `polls/models.py`) a few attributes, as follows:

```
polls/models.py
```

```
class Question(models.Model):
    # ...
    def was_published_recently(self):
        now = timezone.now()
        return now - datetime.timedelta(days=1) <= self.pub_date <= now
        was_published_recently.admin_order_field = 'pub_date'
        was_published_recently.boolean = True
        was_published_recently.short_description = 'Published recently?'
```

For more information on these method properties, see [list\\_display](#).

Edit your `polls/admin.py` file again and add an improvement to the `Question` change list page: filters using the [list\\_filter](#). Add the following line to `QuestionAdmin`:

```
list_filter = ['pub_date']
```

That adds a “Filter” sidebar that lets people filter the change list by the `pub_date` field:

The screenshot shows the Django admin interface for the 'Questions' app. At the top, there is a breadcrumb trail: 'Home > Polls > Questions'. Below this is a header bar with 'Select question to change' on the left and an 'ADD QUESTION +' button on the right. The main content area features an 'Action:' dropdown menu with a 'Go' button and a '0 of 1 selected' indicator. Below the action bar is a table with the following columns: 'QUESTION TEXT', 'DATE PUBLISHED', and 'PUBLISHED RECENTLY?'. The table contains one row with the question 'What's up?' published on 'Sept. 3, 2015, 9:16 p.m.' and a red plus icon in the 'PUBLISHED RECENTLY?' column. Below the table, it says '1 question'. On the right side, there is a 'FILTER' sidebar with a blue header. Under the header, it says 'By date published' and lists filter options: 'Any date', 'Today', 'Past 7 days', 'This month', and 'This year'.

The type of filter displayed depends on the type of field you’re filtering on. Because `pub_date` is a `DateTimeField`, Django knows to give appropriate filter options: “Any date”, “Today”, “Past 7 days”, “This month”, “This year”.

This is shaping up well. Let’s add some search capability:

```
search_fields = ['question_text']
```

That adds a search box at the top of the change list. When somebody enters search terms, Django will search the `question_text` field. You can use as many fields as you’d like – although because it uses a `LIKE` query behind the scenes, limiting the number of search fields to a reasonable number will make it easier for your database to do the search.

Now’s also a good time to note that change lists give you free pagination. The default is to display 100 items per page. [Change list pagination](#), [search boxes](#), [filters](#), [date-hierarchies](#), and [column-header-ordering](#) all work together like you think they should.

## 2.9.4 Customize the admin look and feel

Clearly, having “Django administration” at the top of each admin page is ridiculous. It’s just placeholder text.

That's easy to change, though, using Django's template system. The Django admin is powered by Django itself, and its interfaces use Django's own template system.

## Customizing your *project's* templates

Create a `templates` directory in your project directory (the one that contains `manage.py`). Templates can live anywhere on your filesystem that Django can access. (Django runs as whatever user your server runs.) However, keeping your templates within the project is a good convention to follow.

Open your settings file (`mysite/settings.py`, remember) and add a `DIRS` option in the `TEMPLATES` setting:

```
mysite/settings.py
TEMPLATES = [
    {
        'BACKEND': 'django.template.backends.django.DjangoTemplates',
        'DIRS': [os.path.join(BASE_DIR, 'templates')],
        'APP_DIRS': True,
        'OPTIONS': {
            'context_processors': [
                'django.template.context_processors.debug',
                'django.template.context_processors.request',
                'django.contrib.auth.context_processors.auth',
                'django.contrib.messages.context_processors.messages',
            ],
        },
    ],
]
```

`DIRS` is a list of filesystem directories to check when loading Django templates; it's a search path.

## Organizing templates

Just like the static files, we *could* have all our templates together, in one big templates directory, and it would work perfectly well. However, templates that belong to a particular application should be placed in that application's template directory (e.g. `polls/templates`) rather than the project's (`templates`). We'll discuss in more detail in the *reusable apps tutorial* why we do this.

Now create a directory called `admin` inside `templates`, and copy the template `admin/base_site.html` from within the default Django admin template directory in the source code of Django itself (`django/contrib/admin/templates`) into that directory.

## Where are the Django source files?

If you have difficulty finding where the Django source files are located on your system, run the following command:

```
$ python -c "import django; print(django.__path__)"
```

Then, just edit the file and replace `{{ site_header|default:__('Django administration') }}` (including the curly braces) with your own site's name as you see fit. You should end up with a section of code like:

```
{% block branding %}
<h1 id="site-name"><a href="{% url 'admin:index' %}">Polls Administration</a></h1>
{% endblock %}
```

We use this approach to teach you how to override templates. In an actual project, you would probably use the `django.contrib.admin.AdminSite.site_header` attribute to more easily make this particular customization.

This template file contains lots of text like `{% block branding %}` and `{{ title }}`. The `{%` and `{{` tags are part of Django’s template language. When Django renders `admin/base_site.html`, this template language will be evaluated to produce the final HTML page, just like we saw in [Tutorial 3](#).

Note that any of Django’s default admin templates can be overridden. To override a template, just do the same thing you did with `base_site.html` – copy it from the default directory into your custom directory, and make changes.

## Customizing your *application’s* templates

Astute readers will ask: But if `DIRS` was empty by default, how was Django finding the default admin templates? The answer is that, since `APP_DIRS` is set to `True`, Django automatically looks for a `templates/` subdirectory within each application package, for use as a fallback (don’t forget that `django.contrib.admin` is an application).

Our poll application is not very complex and doesn’t need custom admin templates. But if it grew more sophisticated and required modification of Django’s standard admin templates for some of its functionality, it would be more sensible to modify the *application’s* templates, rather than those in the *project*. That way, you could include the polls application in any new project and be assured that it would find the custom templates it needed.

See the [template loading documentation](#) for more information about how Django finds its templates.

## 2.9.5 Customize the admin index page

On a similar note, you might want to customize the look and feel of the Django admin index page.

By default, it displays all the apps in `INSTALLED_APPS` that have been registered with the admin application, in alphabetical order. You may want to make significant changes to the layout. After all, the index is probably the most important page of the admin, and it should be easy to use.

The template to customize is `admin/index.html`. (Do the same as with `admin/base_site.html` in the previous section – copy it from the default directory to your custom template directory). Edit the file, and you’ll see it uses a template variable called `app_list`. That variable contains every installed Django app. Instead of using that, you can hard-code links to object-specific admin pages in whatever way you think is best.

## 2.9.6 What’s next?

The beginner tutorial ends here. In the meantime, you might want to check out some pointers on [where to go from here](#).

If you are familiar with Python packaging and interested in learning how to turn polls into a “reusable app”, check out [Advanced tutorial: How to write reusable apps](#).

## 2.10 Advanced tutorial: How to write reusable apps

This advanced tutorial begins where [Tutorial 7](#) left off. We’ll be turning our Web-poll into a standalone Python package you can reuse in new projects and share with other people.

If you haven’t recently completed Tutorials 1–7, we encourage you to review these so that your example project matches the one described below.

## 2.10.1 Reusability matters

It's a lot of work to design, build, test and maintain a web application. Many Python and Django projects share common problems. Wouldn't it be great if we could save some of this repeated work?

Reusability is the way of life in Python. The [Python Package Index \(PyPI\)](#) has a vast range of packages you can use in your own Python programs. Check out [Django Packages](#) for existing reusable apps you could incorporate in your project. Django itself is also just a Python package. This means that you can take existing Python packages or Django apps and compose them into your own web project. You only need to write the parts that make your project unique.

Let's say you were starting a new project that needed a polls app like the one we've been working on. How do you make this app reusable? Luckily, you're well on the way already. In [Tutorial 3](#), we saw how we could decouple polls from the project-level URLconf using an `include`. In this tutorial, we'll take further steps to make the app easy to use in new projects and ready to publish for others to install and use.

---

### Package? App?

A Python [package](#) provides a way of grouping related Python code for easy reuse. A package contains one or more files of Python code (also known as “modules”).

A package can be imported with `import foo.bar` or `from foo import bar`. For a directory (like `polls`) to form a package, it must contain a special file `__init__.py`, even if this file is empty.

A Django *application* is just a Python package that is specifically intended for use in a Django project. An application may use common Django conventions, such as having `models`, `tests`, `urls`, and `views` submodules.

Later on we use the term *packaging* to describe the process of making a Python package easy for others to install. It can be a little confusing, we know.

---

## 2.10.2 Your project and your reusable app

After the previous tutorials, our project should look like this:

```
mysite/
  manage.py
  mysite/
    __init__.py
    settings.py
    urls.py
    wsgi.py
  polls/
    __init__.py
    admin.py
    migrations/
      __init__.py
      0001_initial.py
    models.py
    static/
      polls/
        images/
          background.gif
        style.css
    templates/
      polls/
        detail.html
        index.html
```

```
        results.html
    tests.py
    urls.py
    views.py
templates/
    admin/
        base_site.html
```

You created `mysite/templates` in [Tutorial 7](#), and `polls/templates` in [Tutorial 3](#). Now perhaps it is clearer why we chose to have separate template directories for the project and application: everything that is part of the `polls` application is in `polls`. It makes the application self-contained and easier to drop into a new project.

The `polls` directory could now be copied into a new Django project and immediately reused. It's not quite ready to be published though. For that, we need to package the app to make it easy for others to install.

### 2.10.3 Installing some prerequisites

The current state of Python packaging is a bit muddled with various tools. For this tutorial, we're going to use `setuptools` to build our package. It's the recommended packaging tool (merged with the `distribute` fork). We'll also be using `pip` to install and uninstall it. You should install these two packages now. If you need help, you can refer to [how to install Django with pip](#). You can install `setuptools` the same way.

### 2.10.4 Packaging your app

Python *packaging* refers to preparing your app in a specific format that can be easily installed and used. Django itself is packaged very much like this. For a small app like `polls`, this process isn't too difficult.

1. First, create a parent directory for `polls`, outside of your Django project. Call this directory `django-polls`.

---

#### Choosing a name for your app

When choosing a name for your package, check resources like PyPI to avoid naming conflicts with existing packages. It's often useful to prepend `django-` to your module name when creating a package to distribute. This helps others looking for Django apps identify your app as Django specific.

Application labels (that is, the final part of the dotted path to application packages) *must* be unique in [INSTALLED\\_APPS](#). Avoid using the same label as any of the Django *contrib packages*, for example `auth`, `admin`, or `messages`.

---

2. Move the `polls` directory into the `django-polls` directory.
3. Create a file `django-polls/README.rst` with the following contents:

```
django-polls/README.rst
```

```
=====  
Polls  
=====
```

```
Polls is a simple Django app to conduct Web-based polls. For each  
question, visitors can choose between a fixed number of answers.
```

```
Detailed documentation is in the "docs" directory.
```

```
Quick start  
-----
```

1. Add "polls" to your INSTALLED\_APPS setting like this::

```
INSTALLED_APPS = [
    ...
    'polls',
]
```

2. Include the polls URLconf in your project urls.py like this::

```
url(r'^polls/', include('polls.urls')),
```

3. Run `python manage.py migrate` to create the polls models.

4. Start the development server and visit `http://127.0.0.1:8000/admin/` to create a poll (you'll need the Admin app enabled).

5. Visit `http://127.0.0.1:8000/polls/` to participate in the poll.

4. Create a `django-polls/LICENSE` file. Choosing a license is beyond the scope of this tutorial, but suffice it to say that code released publicly without a license is *useless*. Django and many Django-compatible apps are distributed under the BSD license; however, you're free to pick your own license. Just be aware that your licensing choice will affect who is able to use your code.
5. Next we'll create a `setup.py` file which provides details about how to build and install the app. A full explanation of this file is beyond the scope of this tutorial, but the [setuptools docs](#) have a good explanation. Create a file `django-polls/setup.py` with the following contents:

```
django-polls/setup.py

import os
from setuptools import find_packages, setup

with open(os.path.join(os.path.dirname(__file__), 'README.rst')) as readme:
    README = readme.read()

# allow setup.py to be run from any path
os.chdir(os.path.normpath(os.path.join(os.path.abspath(__file__), os.pardir)))

setup(
    name='django-polls',
    version='0.1',
    packages=find_packages(),
    include_package_data=True,
    license='BSD License', # example license
    description='A simple Django app to conduct Web-based polls.',
    long_description=README,
    url='https://www.example.com/',
    author='Your Name',
    author_email='yourname@example.com',
    classifiers=[
        'Environment :: Web Environment',
        'Framework :: Django',
        'Framework :: Django :: X.Y', # replace "X.Y" as appropriate
        'Intended Audience :: Developers',
        'License :: OSI Approved :: BSD License', # example license
        'Operating System :: OS Independent',
        'Programming Language :: Python',
        # Replace these appropriately if you are stuck on Python 2.
        'Programming Language :: Python :: 3',
    ],
)
```

```
'Programming Language :: Python :: 3.4',
'Programming Language :: Python :: 3.5',
'Topic :: Internet :: WWW/HTTP',
'Topic :: Internet :: WWW/HTTP :: Dynamic Content',
],
)
```

6. Only Python modules and packages are included in the package by default. To include additional files, we'll need to create a `MANIFEST.in` file. The `setuptools` docs referred to in the previous step discuss this file in more details. To include the templates, the `README.rst` and our `LICENSE` file, create a file `django-polls/MANIFEST.in` with the following contents:

```
django-polls/MANIFEST.in

include LICENSE
include README.rst
recursive-include polls/static *
recursive-include polls/templates *
```

7. It's optional, but recommended, to include detailed documentation with your app. Create an empty directory `django-polls/docs` for future documentation. Add an additional line to `django-polls/MANIFEST.in`:

```
recursive-include docs *
```

Note that the `docs` directory won't be included in your package unless you add some files to it. Many Django apps also provide their documentation online through sites like [readthedocs.org](http://readthedocs.org).

8. Try building your package with `python setup.py sdist` (run from inside `django-polls`). This creates a directory called `dist` and builds your new package, `django-polls-0.1.tar.gz`.

For more information on packaging, see Python's [Tutorial on Packaging and Distributing Projects](#).

## 2.10.5 Using your own package

Since we moved the `polls` directory out of the project, it's no longer working. We'll now fix this by installing our new `django-polls` package.

---

### Installing as a user library

The following steps install `django-polls` as a user library. Per-user installs have a lot of advantages over installing the package system-wide, such as being usable on systems where you don't have administrator access as well as preventing the package from affecting system services and other users of the machine.

Note that per-user installations can still affect the behavior of system tools that run as that user, so `virtualenv` is a more robust solution (see below).

1. To install the package, use `pip` (you already *installed it*, right?):

```
pip install --user django-polls/dist/django-polls-0.1.tar.gz
```

2. With luck, your Django project should now work correctly again. Run the server again to confirm this.
3. To uninstall the package, use `pip`:

```
pip uninstall django-polls
```

## 2.10.6 Publishing your app

Now that we've packaged and tested `django-polls`, it's ready to share with the world! If this wasn't just an example, you could now:

- Email the package to a friend.
- Upload the package on your website.
- Post the package on a public repository, such as [the Python Package Index \(PyPI\)](#). [packaging.python.org](#) has a [good tutorial](#) for doing this.

## 2.10.7 Installing Python packages with `virtualenv`

Earlier, we installed the `polls` app as a user library. This has some disadvantages:

- Modifying the user libraries can affect other Python software on your system.
- You won't be able to run multiple versions of this package (or others with the same name).

Typically, these situations only arise once you're maintaining several Django projects. When they do, the best solution is to use `virtualenv`. This tool allows you to maintain multiple isolated Python environments, each with its own copy of the libraries and package namespace.

## 2.11 What to read next

So you've read all the *introductory material* and have decided you'd like to keep using Django. We've only just scratched the surface with this intro (in fact, if you've read every single word, you've read about 5% of the overall documentation).

So what's next?

Well, we've always been big fans of learning by doing. At this point you should know enough to start a project of your own and start fooling around. As you need to learn new tricks, come back to the documentation.

We've put a lot of effort into making Django's documentation useful, easy to read and as complete as possible. The rest of this document explains more about how the documentation works so that you can get the most out of it.

(Yes, this is documentation about documentation. Rest assured we have no plans to write a document about how to read the document about documentation.)

### 2.11.1 Finding documentation

Django's got a *lot* of documentation – almost 450,000 words and counting – so finding what you need can sometimes be tricky. A few good places to start are the search and the `genindex`.

Or you can just browse around!

### 2.11.2 How the documentation is organized

Django's main documentation is broken up into “chunks” designed to fill different needs:

- The *introductory material* is designed for people new to Django – or to Web development in general. It doesn't cover anything in depth, but instead gives a high-level overview of how developing in Django “feels”.

- The *topic guides*, on the other hand, dive deep into individual parts of Django. There are complete guides to Django’s *model system*, *template engine*, *forms framework*, and much more.

This is probably where you’ll want to spend most of your time; if you work your way through these guides you should come out knowing pretty much everything there is to know about Django.

- Web development is often broad, not deep – problems span many domains. We’ve written a set of *how-to guides* that answer common “How do I ...?” questions. Here you’ll find information about *generating PDFs with Django*, *writing custom template tags*, and more.

Answers to really common questions can also be found in the *FAQ*.

- The guides and how-to’s don’t cover every single class, function, and method available in Django – that would be overwhelming when you’re trying to learn. Instead, details about individual classes, functions, methods, and modules are kept in the *reference*. This is where you’ll turn to find the details of a particular function or whatever you need.
- If you are interested in deploying a project for public use, our docs have *several guides* for various deployment setups as well as a *deployment checklist* for some things you’ll need to think about.
- Finally, there’s some “specialized” documentation not usually relevant to most developers. This includes the *release notes* and *internals documentation* for those who want to add code to Django itself, and a *few other things that simply don’t fit elsewhere*.

### 2.11.3 How documentation is updated

Just as the Django code base is developed and improved on a daily basis, our documentation is consistently improving. We improve documentation for several reasons:

- To make content fixes, such as grammar/typo corrections.
- To add information and/or examples to existing sections that need to be expanded.
- To document Django features that aren’t yet documented. (The list of such features is shrinking but exists nonetheless.)
- To add documentation for new features as new features get added, or as Django APIs or behaviors change.

Django’s documentation is kept in the same source control system as its code. It lives in the `docs` directory of our Git repository. Each document online is a separate text file in the repository.

### 2.11.4 Where to get it

You can read Django documentation in several ways. They are, in order of preference:

#### On the Web

The most recent version of the Django documentation lives at <https://docs.djangoproject.com/en/dev/>. These HTML pages are generated automatically from the text files in source control. That means they reflect the “latest and greatest” in Django – they include the very latest corrections and additions, and they discuss the latest Django features, which may only be available to users of the Django development version. (See “Differences between versions” below.)

We encourage you to help improve the docs by submitting changes, corrections and suggestions in the [ticket system](#). The Django developers actively monitor the ticket system and use your feedback to improve the documentation for everybody.

Note, however, that tickets should explicitly relate to the documentation, rather than asking broad tech-support questions. If you need help with your particular Django setup, try the *django-users* mailing list or the `#django` IRC channel instead.

## In plain text

For offline reading, or just for convenience, you can read the Django documentation in plain text.

If you're using an official release of Django, note that the zipped package (tarball) of the code includes a `docs/` directory, which contains all the documentation for that release.

If you're using the development version of Django (aka "trunk"), note that the `docs/` directory contains all of the documentation. You can update your Git checkout to get the latest changes.

One low-tech way of taking advantage of the text documentation is by using the Unix `grep` utility to search for a phrase in all of the documentation. For example, this will show you each mention of the phrase "max\_length" in any Django document:

```
$ grep -r max_length /path/to/django/docs/
```

## As HTML, locally

You can get a local copy of the HTML documentation following a few easy steps:

- Django's documentation uses a system called [Sphinx](#) to convert from plain text to HTML. You'll need to install Sphinx by either downloading and installing the package from the Sphinx website, or with `pip`:

```
$ pip install Sphinx
```

- Then, just use the included `Makefile` to turn the documentation into HTML:

```
$ cd path/to/django/docs
$ make html
```

You'll need [GNU Make](#) installed for this.

If you're on Windows you can alternatively use the included batch file:

```
cd path\to\django\docs
make.bat html
```

- The HTML documentation will be placed in `docs/_build/html`.

### 2.11.5 Differences between versions

As previously mentioned, the text documentation in our Git repository contains the "latest and greatest" changes and additions. These changes often include documentation of new features added in the Django development version – the Git ("trunk") version of Django. For that reason, it's worth pointing out our policy on keeping straight the documentation for various versions of the framework.

We follow this policy:

- The primary documentation on [djangoproject.com](#) is an HTML version of the latest docs in Git. These docs always correspond to the latest official Django release, plus whatever features we've added/changed in the framework *since* the latest release.

- As we add features to Django’s development version, we try to update the documentation in the same Git commit transaction.
- To distinguish feature changes/additions in the docs, we use the phrase: “New in version X.Y”, being X.Y the next release version (hence, the one being developed).
- Documentation fixes and improvements may be backported to the last release branch, at the discretion of the committer, however, once a version of Django is *no longer supported*, that version of the docs won’t get any further updates.
- The [main documentation Web page](#) includes links to documentation for all previous versions. Be sure you are using the version of the docs corresponding to the version of Django you are using!

## 2.12 Writing your first patch for Django

### 2.12.1 Introduction

Interested in giving back to the community a little? Maybe you’ve found a bug in Django that you’d like to see fixed, or maybe there’s a small feature you want added.

Contributing back to Django itself is the best way to see your own concerns addressed. This may seem daunting at first, but it’s really pretty simple. We’ll walk you through the entire process, so you can learn by example.

#### Who’s this tutorial for?

##### See also:

If you are looking for a reference on how to submit patches, see the [Submitting patches](#) documentation.

For this tutorial, we expect that you have at least a basic understanding of how Django works. This means you should be comfortable going through the existing tutorials on [writing your first Django app](#). In addition, you should have a good understanding of Python itself. But if you don’t, [Dive Into Python](#) is a fantastic (and free) online book for beginning Python programmers.

Those of you who are unfamiliar with version control systems and Trac will find that this tutorial and its links include just enough information to get started. However, you’ll probably want to read some more about these different tools if you plan on contributing to Django regularly.

For the most part though, this tutorial tries to explain as much as possible, so that it can be of use to the widest audience.

---

#### Where to get help:

If you’re having trouble going through this tutorial, please post a message to [django-developers](#) or drop by [#django-dev](#) on [irc.freenode.net](#) to chat with other Django users who might be able to help.

---

#### What does this tutorial cover?

We’ll be walking you through contributing a patch to Django for the first time. By the end of this tutorial, you should have a basic understanding of both the tools and the processes involved. Specifically, we’ll be covering the following:

- Installing Git.
- How to download a development copy of Django.

- Running Django’s test suite.
- Writing a test for your patch.
- Writing the code for your patch.
- Testing your patch.
- Submitting a pull request.
- Where to look for more information.

Once you’re done with the tutorial, you can look through the rest of *Django’s documentation on contributing*. It contains lots of great information and is a must read for anyone who’d like to become a regular contributor to Django. If you’ve got questions, it’s probably got the answers.

---

### Python 3 required!

This tutorial assumes you are using Python 3. Get the latest version at [Python’s download page](#) or with your operating system’s package manager.

---

---

### For Windows users

When installing Python on Windows, make sure you check the option “Add python.exe to Path”, so that it is always available on the command line.

---

## 2.12.2 Code of Conduct

As a contributor, you can help us keep the Django community open and inclusive. Please read and follow our [Code of Conduct](#).

## 2.12.3 Installing Git

For this tutorial, you’ll need Git installed to download the current development version of Django and to generate patch files for the changes you make.

To check whether or not you have Git installed, enter `git` into the command line. If you get messages saying that this command could not be found, you’ll have to download and install it, see [Git’s download page](#).

---

### For Windows users

When installing Git on Windows, it is recommended that you pick the “Git Bash” option so that Git runs in its own shell. This tutorial assumes that’s how you have installed it.

---

If you’re not that familiar with Git, you can always find out more about its commands (once it’s installed) by typing `git help` into the command line.

## 2.12.4 Getting a copy of Django’s development version

The first step to contributing to Django is to get a copy of the source code. First, [fork Django on GitHub](#). Then, from the command line, use the `cd` command to navigate to the directory where you’ll want your local copy of Django to live.

Download the Django source code repository using the following command:

```
$ git clone git@github.com:YourGitHubName/django.git
```

Now that you have a local copy of Django, you can install it just like you would install any package using `pip`. The most convenient way to do so is by using a *virtual environment* (or `virtualenv`) which is a feature built into Python that allows you to keep a separate directory of installed packages for each of your projects so that they don't interfere with each other.

It's a good idea to keep all your virtualenvs in one place, for example in `~/.virtualenvs/` in your home directory. Create it if it doesn't exist yet:

```
$ mkdir ~/.virtualenvs
```

Now create a new virtualenv by running:

```
$ python3 -m venv ~/.virtualenvs/djangodev
```

The path is where the new environment will be saved on your computer.

---

### For Windows users

Using the built-in `venv` module will not work if you are also using the Git Bash shell on Windows, since activation scripts are only created for the system shell (`.bat`) and PowerShell (`.ps1`). Use the `virtualenv` package instead:

```
$ pip install virtualenv
$ virtualenv ~/.virtualenvs/djangodev
```

---

### For Ubuntu users

On some versions of Ubuntu the above command might fail. Use the `virtualenv` package instead, first making sure you have `pip3`:

```
$ sudo apt-get install python3-pip
$ # Prefix the next command with sudo if it gives a permission denied error
$ pip3 install virtualenv
$ virtualenv --python=$(which python3) ~/.virtualenvs/djangodev
```

The final step in setting up your virtualenv is to activate it:

```
$ source ~/.virtualenvs/djangodev/bin/activate
```

If the `source` command is not available, you can try using a dot instead:

```
$ . ~/.virtualenvs/djangodev/bin/activate
```

---

### For Windows users

To activate your virtualenv on Windows, run:

```
$ source ~/virtualenvs/djangodev/Scripts/activate
```

You have to activate the `virtualenv` whenever you open a new terminal window. `virtualenvwrapper` is a useful tool for making this more convenient.

Anything you install through `pip` from now on will be installed in your new `virtualenv`, isolated from other environments and system-wide packages. Also, the name of the currently activated `virtualenv` is displayed on the command line to help you keep track of which one you are using. Go ahead and install the previously cloned copy of Django:

```
$ pip install -e /path/to/your/local/clone/django/
```

The installed version of Django is now pointing at your local copy. You will immediately see any changes you make to it, which is of great help when writing your first patch.

## 2.12.5 Rolling back to a previous revision of Django

For this tutorial, we'll be using ticket [#24788](#) as a case study, so we'll rewind Django's version history in git to before that ticket's patch was applied. This will allow us to go through all of the steps involved in writing that patch from scratch, including running Django's test suite.

**Keep in mind that while we'll be using an older revision of Django's trunk for the purposes of the tutorial below, you should always use the current development revision of Django when working on your own patch for a ticket!**

---

**Note:** The patch for this ticket was written by Paweł Marczewski, and it was applied to Django as [commit 4df7e8483b2679fc1cba3410f08960bac6f51115](#). Consequently, we'll be using the revision of Django just prior to that, [commit 4ccfc4439a7add24f8db4ef3960d02ef8ae09887](#).

---

Navigate into Django's root directory (that's the one that contains `django`, `docs`, `tests`, `AUTHORS`, etc.). You can then check out the older revision of Django that we'll be using in the tutorial below:

```
$ git checkout 4ccfc4439a7add24f8db4ef3960d02ef8ae09887
```

## 2.12.6 Running Django's test suite for the first time

When contributing to Django it's very important that your code changes don't introduce bugs into other areas of Django. One way to check that Django still works after you make your changes is by running Django's test suite. If all the tests still pass, then you can be reasonably sure that your changes haven't completely broken Django. If you've never run Django's test suite before, it's a good idea to run it once beforehand just to get familiar with what its output is supposed to look like.

Before running the test suite, install its dependencies by first `cd`-ing into the Django `tests/` directory and then running:

```
$ pip install -r requirements/py3.txt
```

If you encounter an error during the installation, your system might be missing a dependency for one or more of the Python packages. Consult the failing package's documentation or search the Web with the error message that you encounter.

Now we are ready to run the test suite. If you're using GNU/Linux, Mac OS X or some other flavor of Unix, run:

```
$ ./runtests.py
```

Now sit back and relax. Django's entire test suite has over 9,600 different tests, so it can take anywhere from 5 to 15 minutes to run, depending on the speed of your computer.

While Django’s test suite is running, you’ll see a stream of characters representing the status of each test as it’s run. E indicates that an error was raised during a test, and F indicates that a test’s assertions failed. Both of these are considered to be test failures. Meanwhile, x and s indicated expected failures and skipped tests, respectively. Dots indicate passing tests.

Skipped tests are typically due to missing external libraries required to run the test; see [Running all the tests](#) for a list of dependencies and be sure to install any for tests related to the changes you are making (we won’t need any for this tutorial). Some tests are specific to a particular database backend and will be skipped if not testing with that backend. SQLite is the database backend for the default settings. To run the tests using a different backend, see [Using another settings module](#).

Once the tests complete, you should be greeted with a message informing you whether the test suite passed or failed. Since you haven’t yet made any changes to Django’s code, the entire test suite **should** pass. If you get failures or errors make sure you’ve followed all of the previous steps properly. See [Running the unit tests](#) for more information. If you’re using Python 3.5+, there will be a couple failures related to deprecation warnings that you can ignore. These failures have since been fixed in Django.

Note that the latest Django trunk may not always be stable. When developing against trunk, you can check [Django’s continuous integration builds](#) to determine if the failures are specific to your machine or if they are also present in Django’s official builds. If you click to view a particular build, you can view the “Configuration Matrix” which shows failures broken down by Python version and database backend.

---

**Note:** For this tutorial and the ticket we’re working on, testing against SQLite is sufficient, however, it’s possible (and sometimes necessary) to [run the tests using a different database](#).

---

## 2.12.7 Creating a branch for your patch

Before making any changes, create a new branch for the ticket:

```
$ git checkout -b ticket_24788
```

You can choose any name that you want for the branch, “ticket\_24788” is an example. All changes made in this branch will be specific to the ticket and won’t affect the main copy of the code that we cloned earlier.

## 2.12.8 Writing some tests for your ticket

In most cases, for a patch to be accepted into Django it has to include tests. For bug fix patches, this means writing a regression test to ensure that the bug is never reintroduced into Django later on. A regression test should be written in such a way that it will fail while the bug still exists and pass once the bug has been fixed. For patches containing new features, you’ll need to include tests which ensure that the new features are working correctly. They too should fail when the new feature is not present, and then pass once it has been implemented.

A good way to do this is to write your new tests first, before making any changes to the code. This style of development is called [test-driven development](#) and can be applied to both entire projects and single patches. After writing your tests, you then run them to make sure that they do indeed fail (since you haven’t fixed that bug or added that feature yet). If your new tests don’t fail, you’ll need to fix them so that they do. After all, a regression test that passes regardless of whether a bug is present is not very helpful at preventing that bug from reoccurring down the road.

Now for our hands-on example.

## Writing some tests for ticket #24788

Ticket #24788 proposes a small feature addition: the ability to specify the class level attribute `prefix` on Form classes, so that:

[...] forms which ship with apps could effectively namespace themselves such that N overlapping form fields could be POSTed at once and resolved to the correct form.

In order to resolve this ticket, we'll add a `prefix` attribute to the `BaseForm` class. When creating instances of this class, passing a prefix to the `__init__()` method will still set that prefix on the created instance. But not passing a prefix (or passing `None`) will use the class-level prefix. Before we make those changes though, we're going to write a couple tests to verify that our modification functions correctly and continues to function correctly in the future.

Navigate to Django's `tests/forms_tests/tests/` folder and open the `test_forms.py` file. Add the following code on line 1674 right before the `test_forms_with_null_boolean` function:

```
def test_class_prefix(self):
    # Prefix can be also specified at the class level.
    class Person(Form):
        first_name = CharField()
        prefix = 'foo'

    p = Person()
    self.assertEqual(p.prefix, 'foo')

    p = Person(prefix='bar')
    self.assertEqual(p.prefix, 'bar')
```

This new test checks that setting a class level prefix works as expected, and that passing a `prefix` parameter when creating an instance still works too.

### But this testing thing looks kinda hard...

If you've never had to deal with tests before, they can look a little hard to write at first glance. Fortunately, testing is a *very* big subject in computer programming, so there's lots of information out there:

- A good first look at writing tests for Django can be found in the documentation on [Writing and running tests](#).
- Dive Into Python (a free online book for beginning Python developers) includes a great [introduction to Unit Testing](#).
- After reading those, if you want something a little meatier to sink your teeth into, there's always the Python `unittest` documentation.

## Running your new test

Remember that we haven't actually made any modifications to `BaseForm` yet, so our tests are going to fail. Let's run all the tests in the `forms_tests` folder to make sure that's really what happens. From the command line, `cd` into the Django `tests/` directory and run:

```
$ ./runtests.py forms_tests
```

If the tests ran correctly, you should see one failure corresponding to the test method we added. If all of the tests passed, then you'll want to make sure that you added the new test shown above to the appropriate folder and class.

## 2.12.9 Writing the code for your ticket

Next we'll be adding the functionality described in ticket #24788 to Django.

### Writing the code for ticket #24788

Navigate to the `django/django/forms/` folder and open the `forms.py` file. Find the `BaseForm` class on line 72 and add the `prefix` class attribute right after the `field_order` attribute:

```
class BaseForm(object):
    # This is the main implementation of all the Form logic. Note that this
    # class is different than Form. See the comments by the Form class for
    # more information. Any improvements to the form API should be made to
    # *this* class, not to the Form class.
    field_order = None
    prefix = None
```

### Verifying your test now passes

Once you're done modifying Django, we need to make sure that the tests we wrote earlier pass, so we can see whether the code we wrote above is working correctly. To run the tests in the `forms_tests` folder, `cd` into the Django `tests/` directory and run:

```
$ ./runtests.py forms_tests
```

Oops, good thing we wrote those tests! You should still see one failure with the following exception:

```
AssertionError: None != 'foo'
```

We forgot to add the conditional statement in the `__init__` method. Go ahead and change `self.prefix = prefix` that is now on line 87 of `django/forms/forms.py`, adding a conditional statement:

```
if prefix is not None:
    self.prefix = prefix
```

Re-run the tests and everything should pass. If it doesn't, make sure you correctly modified the `BaseForm` class as shown above and copied the new test correctly.

## 2.12.10 Running Django's test suite for the second time

Once you've verified that your patch and your test are working correctly, it's a good idea to run the entire Django test suite just to verify that your change hasn't introduced any bugs into other areas of Django. While successfully passing the entire test suite doesn't guarantee your code is bug free, it does help identify many bugs and regressions that might otherwise go unnoticed.

To run the entire Django test suite, `cd` into the Django `tests/` directory and run:

```
$ ./runtests.py
```

As long as you don't see any failures, you're good to go.

## 2.12.11 Writing Documentation

This is a new feature, so it should be documented. Add the following section on line 1068 (at the end of the file) of `django/docs/ref/forms/api.txt`:

The prefix can also be specified on the form class::

```
>>> class PersonForm(forms.Form):
...     ...
...     prefix = 'person'

.. versionadded:: 1.9

    The ability to specify ``prefix`` on the form class was added.
```

Since this new feature will be in an upcoming release it is also added to the release notes for Django 1.9, on line 164 under the “Forms” section in the file `docs/releases/1.9.txt`:

```
* A form prefix can be specified inside a form class, not only when
  instantiating a form. See :ref:`form-prefix` for details.
```

For more information on writing documentation, including an explanation of what the `versionadded` bit is all about, see [Writing documentation](#). That page also includes an explanation of how to build a copy of the documentation locally, so you can preview the HTML that will be generated.

## 2.12.12 Previewing your changes

Now it’s time to go through all the changes made in our patch. To display the differences between your current copy of Django (with your changes) and the revision that you initially checked out earlier in the tutorial:

```
$ git diff
```

Use the arrow keys to move up and down.

```

```

When you're done previewing the patch, hit the `q` key to return to the command line. If the patch's content looked okay, it's time to commit the changes.

### 2.12.13 Committing the changes in the patch

To commit the changes:

```
$ git commit -a
```

This opens up a text editor to type the commit message. Follow the *commit message guidelines* and write a message like:

```
Fixed #24788 -- Allowed Forms to specify a prefix at the class level.
```

### 2.12.14 Pushing the commit and making a pull request

After committing the patch, send it to your fork on GitHub (substitute “ticket\_24788” with the name of your branch if it's different):

```
$ git push origin ticket_24788
```

You can create a pull request by visiting the [Django GitHub page](#). You'll see your branch under “Your recently pushed branches”. Click “Compare & pull request” next to it.

Please don't do it for this tutorial, but on the next page that displays a preview of the patch, you would click “Create pull request”.

### 2.12.15 Next steps

Congratulations, you've learned how to make a pull request to Django! Details of more advanced techniques you may need are in *Working with Git and GitHub*.

Now you can put those skills to good use by helping to improve Django's codebase.

#### More information for new contributors

Before you get too into writing patches for Django, there's a little more information on contributing that you should probably take a look at:

- You should make sure to read Django's documentation on *claiming tickets and submitting patches*. It covers Trac etiquette, how to claim tickets for yourself, expected coding style for patches, and many other important details.
- First time contributors should also read Django's *documentation for first time contributors*. It has lots of good advice for those of us who are new to helping out with Django.
- After those, if you're still hungry for more information about contributing, you can always browse through the rest of *Django's documentation on contributing*. It contains a ton of useful information and should be your first source for answering any questions you might have.

## Finding your first real ticket

Once you've looked through some of that information, you'll be ready to go out and find a ticket of your own to write a patch for. Pay special attention to tickets with the “easy pickings” criterion. These tickets are often much simpler in nature and are great for first time contributors. Once you're familiar with contributing to Django, you can move on to writing patches for more difficult and complicated tickets.

If you just want to get started already (and nobody would blame you!), try taking a look at the list of [easy tickets that need patches](#) and the [easy tickets that have patches which need improvement](#). If you're familiar with writing tests, you can also look at the list of [easy tickets that need tests](#). Just remember to follow the guidelines about claiming tickets that were mentioned in the link to Django's documentation on *claiming tickets and submitting patches*.

## What's next after creating a pull request?

After a ticket has a patch, it needs to be reviewed by a second set of eyes. After submitting a pull request, update the ticket metadata by setting the flags on the ticket to say “has patch”, “doesn't need tests”, etc, so others can find it for review. Contributing doesn't necessarily always mean writing a patch from scratch. Reviewing existing patches is also a very helpful contribution. See *Triaging tickets* for details.

### See also:

If you're new to [Python](#), you might want to start by getting an idea of what the language is like. Django is 100% Python, so if you've got minimal comfort with Python you'll probably get a lot more out of Django.

If you're new to programming entirely, you might want to start with this [list of Python resources for non-programmers](#)

If you already know a few other languages and want to get up to speed with Python quickly, we recommend [Dive Into Python](#). If that's not quite your style, there are many other [books about Python](#).

Introductions to all the key parts of Django you'll need to know:

### 3.1 How to install Django

This document will get you up and running with Django.

#### 3.1.1 Install Python

Being a Python Web framework, Django requires Python. See *What Python version can I use with Django?* for details. Get the latest version of Python at <https://www.python.org/download/> or with your operating system's package manager.

---

#### Django on Jython

If you use *Jython* (a Python implementation for the Java platform), you'll need to follow a few additional steps. See *Running Django on Jython* for details.

---

---

#### Python on Windows

If you are just starting with Django and using Windows, you may find *How to install Django on Windows* useful.

---

#### 3.1.2 Install Apache and `mod_wsgi`

If you just want to experiment with Django, skip ahead to the next section; Django includes a lightweight web server you can use for testing, so you won't need to set up Apache until you're ready to deploy Django in production.

If you want to use Django on a production site, use [Apache](#) with `mod_wsgi`. `mod_wsgi` can operate in one of two modes: an embedded mode and a daemon mode. In embedded mode, `mod_wsgi` is similar to `mod_perl` – it embeds Python within Apache and loads Python code into memory when the server starts. Code stays in memory throughout the life of an Apache process, which leads to significant performance gains over other server arrangements. In daemon mode, `mod_wsgi` spawns an independent daemon process that handles requests. The daemon process can run as a different user than the Web server, possibly leading to improved security, and the daemon process can be restarted without restarting the entire Apache Web server, possibly making refreshing your codebase more seamless. Consult the `mod_wsgi` documentation to determine which mode is right for your setup. Make sure you have Apache installed, with the `mod_wsgi` module activated. Django will work with any version of Apache that supports `mod_wsgi`.

See [How to use Django with mod\\_wsgi](#) for information on how to configure `mod_wsgi` once you have it installed.

If you can't use `mod_wsgi` for some reason, fear not: Django supports many other deployment options. One is *uWSGI*; it works very well with [nginx](#). Additionally, Django follows the WSGI spec ([PEP 3333](#)), which allows it to run on a variety of server platforms.

### 3.1.3 Get your database running

If you plan to use Django's database API functionality, you'll need to make sure a database server is running. Django supports many different database servers and is officially supported with [PostgreSQL](#), [MySQL](#), [Oracle](#) and [SQLite](#).

If you are developing a simple project or something you don't plan to deploy in a production environment, [SQLite](#) is generally the simplest option as it doesn't require running a separate server. However, [SQLite](#) has many differences from other databases, so if you are working on something substantial, it's recommended to develop with the same database as you plan on using in production.

In addition to the officially supported databases, there are *backends provided by 3rd parties* that allow you to use other databases with Django.

In addition to a database backend, you'll need to make sure your Python database bindings are installed.

- If you're using [PostgreSQL](#), you'll need the [psycopg2](#) package. Refer to the [PostgreSQL notes](#) for further details.
- If you're using [MySQL](#), you'll need a *DB API driver* like `mysqlclient`. See [notes for the MySQL backend](#) for details.
- If you're using [SQLite](#) you might want to read the [SQLite backend notes](#).
- If you're using [Oracle](#), you'll need a copy of `cx_Oracle`, but please read the [notes for the Oracle backend](#) for details regarding supported versions of both [Oracle](#) and `cx_Oracle`.
- If you're using an unofficial 3rd party backend, please consult the documentation provided for any additional requirements.

If you plan to use Django's `manage.py migrate` command to automatically create database tables for your models (after first installing Django and creating a project), you'll need to ensure that Django has permission to create and alter tables in the database you're using; if you plan to manually create the tables, you can simply grant Django `SELECT`, `INSERT`, `UPDATE` and `DELETE` permissions. After creating a database user with these permissions, you'll specify the details in your project's settings file, see [DATABASES](#) for details.

If you're using Django's *testing framework* to test database queries, Django will need permission to create a test database.

### 3.1.4 Remove any old versions of Django

If you are upgrading your installation of Django from a previous version, you will need to uninstall the old Django version before installing the new version.

If you installed Django using `pip` or `easy_install` previously, installing with `pip` or `easy_install` again will automatically take care of the old version, so you don't need to do it yourself.

If you previously installed Django using `python setup.py install`, uninstalling is as simple as deleting the `django` directory from your Python `site-packages`. To find the directory you need to remove, you can run the following at your shell prompt (not the interactive Python prompt):

```
$ python -c "import django; print(django.__path__)"
```

### 3.1.5 Install the Django code

Installation instructions are slightly different depending on whether you're installing a distribution-specific package, downloading the latest official release, or fetching the latest development version.

It's easy, no matter which way you choose.

#### Installing an official release with `pip`

This is the recommended way to install Django.

1. Install `pip`. The easiest is to use the [standalone pip installer](#). If your distribution already has `pip` installed, you might need to update it if it's outdated. If it's outdated, you'll know because installation won't work.
2. Take a look at [virtualenv](#) and [virtualenvwrapper](#). These tools provide isolated Python environments, which are more practical than installing packages systemwide. They also allow installing packages without administrator privileges. The [contributing tutorial](#) walks through how to create a `virtualenv` on Python 3.
3. After you've created and activated a virtual environment, enter the command `pip install Django` at the shell prompt.

#### Installing a distribution-specific package

Check the [distribution specific notes](#) to see if your platform/distribution provides official Django packages/installers. Distribution-provided packages will typically allow for automatic installation of dependencies and easy upgrade paths; however, these packages will rarely contain the latest release of Django.

#### Installing the development version

---

#### Tracking Django development

If you decide to use the latest development version of Django, you'll want to pay close attention to the [development timeline](#), and you'll want to keep an eye on the [release notes for the upcoming release](#). This will help you stay on top of any new features you might want to use, as well as any changes you'll need to make to your code when updating your copy of Django. (For stable releases, any necessary changes are documented in the release notes.)

If you'd like to be able to update your Django code occasionally with the latest bug fixes and improvements, follow these instructions:

1. Make sure that you have [Git](#) installed and that you can run its commands from a shell. (Enter `git help` at a shell prompt to test this.)
2. Check out Django's main development branch like so:

```
$ git clone git://github.com/django/django.git
```

This will create a directory `django` in your current directory.

3. Make sure that the Python interpreter can load Django's code. The most convenient way to do this is to use [virtualenv](#), [virtualenvwrapper](#), and [pip](#). The [contributing tutorial](#) walks through how to create a virtualenv on Python 3.
4. After setting up and activating the virtualenv, run the following command:

```
$ pip install -e django/
```

This will make Django's code importable, and will also make the `django-admin` utility command available. In other words, you're all set!

When you want to update your copy of the Django source code, just run the command `git pull` from within the `django` directory. When you do this, Git will automatically download any changes.

## 3.2 Models and databases

A model is the single, definitive source of data about your data. It contains the essential fields and behaviors of the data you're storing. Generally, each model maps to a single database table.

### 3.2.1 Models

A model is the single, definitive source of information about your data. It contains the essential fields and behaviors of the data you're storing. Generally, each model maps to a single database table.

The basics:

- Each model is a Python class that subclasses `django.db.models.Model`.
- Each attribute of the model represents a database field.
- With all of this, Django gives you an automatically-generated database-access API; see [Making queries](#).

#### Quick example

This example model defines a `Person`, which has a `first_name` and `last_name`:

```
from django.db import models

class Person(models.Model):
    first_name = models.CharField(max_length=30)
    last_name = models.CharField(max_length=30)
```

`first_name` and `last_name` are *fields* of the model. Each field is specified as a class attribute, and each attribute maps to a database column.

The above `Person` model would create a database table like this:

```
CREATE TABLE myapp_person (
  "id" serial NOT NULL PRIMARY KEY,
  "first_name" varchar(30) NOT NULL,
  "last_name" varchar(30) NOT NULL
);
```

Some technical notes:

- The name of the table, `myapp_person`, is automatically derived from some model metadata but can be overridden. See [Table names](#) for more details.
- An `id` field is added automatically, but this behavior can be overridden. See [Automatic primary key fields](#).
- The `CREATE TABLE` SQL in this example is formatted using PostgreSQL syntax, but it's worth noting Django uses SQL tailored to the database backend specified in your *settings file*.

## Using models

Once you have defined your models, you need to tell Django you're going to *use* those models. Do this by editing your settings file and changing the `INSTALLED_APPS` setting to add the name of the module that contains your `models.py`.

For example, if the models for your application live in the module `myapp.models` (the package structure that is created for an application by the `manage.py startapp` script), `INSTALLED_APPS` should read, in part:

```
INSTALLED_APPS = [
    # ...
    'myapp',
    # ...
]
```

When you add new apps to `INSTALLED_APPS`, be sure to run `manage.py migrate`, optionally making migrations for them first with `manage.py makemigrations`.

## Fields

The most important part of a model – and the only required part of a model – is the list of database fields it defines. Fields are specified by class attributes. Be careful not to choose field names that conflict with the *models API* like `clean`, `save`, or `delete`.

Example:

```
from django.db import models

class Musician(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)
    instrument = models.CharField(max_length=100)

class Album(models.Model):
    artist = models.ForeignKey(Musician, on_delete=models.CASCADE)
    name = models.CharField(max_length=100)
    release_date = models.DateField()
    num_stars = models.IntegerField()
```

## Field types

Each field in your model should be an instance of the appropriate *Field* class. Django uses the field class types to determine a few things:

- The column type, which tells the database what kind of data to store (e.g. INTEGER, VARCHAR, TEXT).
- The default HTML *widget* to use when rendering a form field (e.g. `<input type="text">`, `<select>`).
- The minimal validation requirements, used in Django's admin and in automatically-generated forms.

Django ships with dozens of built-in field types; you can find the complete list in the [model field reference](#). You can easily write your own fields if Django's built-in ones don't do the trick; see [Writing custom model fields](#).

## Field options

Each field takes a certain set of field-specific arguments (documented in the [model field reference](#)). For example, `CharField` (and its subclasses) require a `max_length` argument which specifies the size of the VARCHAR database field used to store the data.

There's also a set of common arguments available to all field types. All are optional. They're fully explained in the [reference](#), but here's a quick summary of the most often-used ones:

**`null`** If `True`, Django will store empty values as NULL in the database. Default is `False`.

**`blank`** If `True`, the field is allowed to be blank. Default is `False`.

Note that this is different than `null`. `null` is purely database-related, whereas `blank` is validation-related. If a field has `blank=True`, form validation will allow entry of an empty value. If a field has `blank=False`, the field will be required.

**`choices`** An iterable (e.g., a list or tuple) of 2-tuples to use as choices for this field. If this is given, the default form widget will be a select box instead of the standard text field and will limit choices to the choices given.

A choices list looks like this:

```
YEAR_IN_SCHOOL_CHOICES = (  
    ('FR', 'Freshman'),  
    ('SO', 'Sophomore'),  
    ('JR', 'Junior'),  
    ('SR', 'Senior'),  
    ('GR', 'Graduate'),  
)
```

The first element in each tuple is the value that will be stored in the database. The second element will be displayed by the default form widget or in a `ModelChoiceField`. Given a model instance, the display value for a choices field can be accessed using the `get_FOO_display()` method. For example:

```
from django.db import models  
  
class Person(models.Model):  
    SHIRT_SIZES = (  
        ('S', 'Small'),  
        ('M', 'Medium'),  
        ('L', 'Large'),  
    )  
    name = models.CharField(max_length=60)  
    shirt_size = models.CharField(max_length=1, choices=SHIRT_SIZES)
```

```
>>> p = Person(name="Fred Flintstone", shirt_size="L")  
>>> p.save()  
>>> p.shirt_size  
'L'
```

```
>>> p.get_shirt_size_display()
'Large'
```

**default** The default value for the field. This can be a value or a callable object. If callable it will be called every time a new object is created.

**help\_text** Extra “help” text to be displayed with the form widget. It’s useful for documentation even if your field isn’t used on a form.

**primary\_key** If `True`, this field is the primary key for the model.

If you don’t specify `primary_key=True` for any fields in your model, Django will automatically add an `IntegerField` to hold the primary key, so you don’t need to set `primary_key=True` on any of your fields unless you want to override the default primary-key behavior. For more, see [Automatic primary key fields](#).

The primary key field is read-only. If you change the value of the primary key on an existing object and then save it, a new object will be created alongside the old one. For example:

```
from django.db import models

class Fruit(models.Model):
    name = models.CharField(max_length=100, primary_key=True)
```

```
>>> fruit = Fruit.objects.create(name='Apple')
>>> fruit.name = 'Pear'
>>> fruit.save()
>>> Fruit.objects.values_list('name', flat=True)
['Apple', 'Pear']
```

**unique** If `True`, this field must be unique throughout the table.

Again, these are just short descriptions of the most common field options. Full details can be found in the [common model field option reference](#).

## Automatic primary key fields

By default, Django gives each model the following field:

```
id = models.AutoField(primary_key=True)
```

This is an auto-incrementing primary key.

If you’d like to specify a custom primary key, just specify `primary_key=True` on one of your fields. If Django sees you’ve explicitly set `Field.primary_key`, it won’t add the automatic `id` column.

Each model requires exactly one field to have `primary_key=True` (either explicitly declared or automatically added).

## Verbose field names

Each field type, except for `ForeignKey`, `ManyToManyField` and `OneToOneField`, takes an optional first positional argument – a verbose name. If the verbose name isn’t given, Django will automatically create it using the field’s attribute name, converting underscores to spaces.

In this example, the verbose name is “person’s first name”:

```
first_name = models.CharField("person's first name", max_length=30)
```

In this example, the verbose name is "first name":

```
first_name = models.CharField(max_length=30)
```

*ForeignKey*, *ManyToManyField* and *OneToOneField* require the first argument to be a model class, so use the *verbose\_name* keyword argument:

```
poll = models.ForeignKey(
    Poll,
    on_delete=models.CASCADE,
    verbose_name="the related poll",
)
sites = models.ManyToManyField(Site, verbose_name="list of sites")
place = models.OneToOneField(
    Place,
    on_delete=models.CASCADE,
    verbose_name="related place",
)
```

The convention is not to capitalize the first letter of the *verbose\_name*. Django will automatically capitalize the first letter where it needs to.

## Relationships

Clearly, the power of relational databases lies in relating tables to each other. Django offers ways to define the three most common types of database relationships: many-to-one, many-to-many and one-to-one.

### Many-to-one relationships

To define a many-to-one relationship, use *django.db.models.ForeignKey*. You use it just like any other *Field* type: by including it as a class attribute of your model.

*ForeignKey* requires a positional argument: the class to which the model is related.

For example, if a *Car* model has a *Manufacturer* – that is, a *Manufacturer* makes multiple cars but each *Car* only has one *Manufacturer* – use the following definitions:

```
from django.db import models

class Manufacturer(models.Model):
    # ...
    pass

class Car(models.Model):
    manufacturer = models.ForeignKey(Manufacturer, on_delete=models.CASCADE)
    # ...
```

You can also create *recursive relationships* (an object with a many-to-one relationship to itself) and *relationships to models not yet defined*; see *the model field reference* for details.

It's suggested, but not required, that the name of a *ForeignKey* field (*manufacturer* in the example above) be the name of the model, lowercase. You can, of course, call the field whatever you want. For example:

```
class Car(models.Model):
    company_that_makes_it = models.ForeignKey(
        Manufacturer,
        on_delete=models.CASCADE,
    )
    # ...
```

**See also:**

*ForeignKey* fields accept a number of extra arguments which are explained in *the model field reference*. These options help define how the relationship should work; all are optional.

For details on accessing backwards-related objects, see the *Following relationships backward example*.

For sample code, see the *Many-to-one relationship model example*.

**Many-to-many relationships**

To define a many-to-many relationship, use *ManyToManyField*. You use it just like any other *Field* type: by including it as a class attribute of your model.

*ManyToManyField* requires a positional argument: the class to which the model is related.

For example, if a *Pizza* has multiple *Topping* objects – that is, a *Topping* can be on multiple pizzas and each *Pizza* has multiple toppings – here’s how you’d represent that:

```
from django.db import models

class Topping(models.Model):
    # ...
    pass

class Pizza(models.Model):
    # ...
    toppings = models.ManyToManyField(Topping)
```

As with *ForeignKey*, you can also create *recursive relationships* (an object with a many-to-many relationship to itself) and *relationships to models not yet defined*.

It’s suggested, but not required, that the name of a *ManyToManyField* (*toppings* in the example above) be a plural describing the set of related model objects.

It doesn’t matter which model has the *ManyToManyField*, but you should only put it in one of the models – not both.

Generally, *ManyToManyField* instances should go in the object that’s going to be edited on a form. In the above example, *toppings* is in *Pizza* (rather than *Topping* having a *pizzas ManyToManyField*) because it’s more natural to think about a pizza having toppings than a topping being on multiple pizzas. The way it’s set up above, the *Pizza* form would let users select the toppings.

**See also:**

See the *Many-to-many relationship model example* for a full example.

*ManyToManyField* fields also accept a number of extra arguments which are explained in *the model field reference*. These options help define how the relationship should work; all are optional.

## Extra fields on many-to-many relationships

When you're only dealing with simple many-to-many relationships such as mixing and matching pizzas and toppings, a standard `ManyToManyField` is all you need. However, sometimes you may need to associate data with the relationship between two models.

For example, consider the case of an application tracking the musical groups which musicians belong to. There is a many-to-many relationship between a person and the groups of which they are a member, so you could use a `ManyToManyField` to represent this relationship. However, there is a lot of detail about the membership that you might want to collect, such as the date at which the person joined the group.

For these situations, Django allows you to specify the model that will be used to govern the many-to-many relationship. You can then put extra fields on the intermediate model. The intermediate model is associated with the `ManyToManyField` using the `through` argument to point to the model that will act as an intermediary. For our musician example, the code would look something like this:

```
from django.db import models

class Person(models.Model):
    name = models.CharField(max_length=128)

    def __str__(self):
        return self.name

class Group(models.Model):
    name = models.CharField(max_length=128)
    members = models.ManyToManyField(Person, through='Membership')

    def __str__(self):
        return self.name

class Membership(models.Model):
    person = models.ForeignKey(Person, on_delete=models.CASCADE)
    group = models.ForeignKey(Group, on_delete=models.CASCADE)
    date_joined = models.DateField()
    invite_reason = models.CharField(max_length=64)
```

When you set up the intermediary model, you explicitly specify foreign keys to the models that are involved in the many-to-many relationship. This explicit declaration defines how the two models are related.

There are a few restrictions on the intermediate model:

- Your intermediate model must contain one - and *only* one - foreign key to the source model (this would be `Group` in our example), or you must explicitly specify the foreign keys Django should use for the relationship using `ManyToManyField.through_fields`. If you have more than one foreign key and `through_fields` is not specified, a validation error will be raised. A similar restriction applies to the foreign key to the target model (this would be `Person` in our example).
- For a model which has a many-to-many relationship to itself through an intermediary model, two foreign keys to the same model are permitted, but they will be treated as the two (different) sides of the many-to-many relationship. If there are *more* than two foreign keys though, you must also specify `through_fields` as above, or a validation error will be raised.
- When defining a many-to-many relationship from a model to itself, using an intermediary model, you *must* use `symmetrical=False` (see [the model field reference](#)).

Now that you have set up your `ManyToManyField` to use your intermediary model (`Membership`, in this case), you're ready to start creating some many-to-many relationships. You do this by creating instances of the intermediate model:

```
>>> ringo = Person.objects.create(name="Ringo Starr")
>>> paul = Person.objects.create(name="Paul McCartney")
>>> beatles = Group.objects.create(name="The Beatles")
>>> m1 = Membership(person=ringo, group=beatles,
...     date_joined=date(1962, 8, 16),
...     invite_reason="Needed a new drummer.")
>>> m1.save()
>>> beatles.members.all()
<QuerySet [<Person: Ringo Starr>]>
>>> ringo.group_set.all()
<QuerySet [<Group: The Beatles>]>
>>> m2 = Membership.objects.create(person=paul, group=beatles,
...     date_joined=date(1960, 8, 1),
...     invite_reason="Wanted to form a band.")
>>> beatles.members.all()
<QuerySet [<Person: Ringo Starr>, <Person: Paul McCartney>]>
```

Unlike normal many-to-many fields, you *can't* use `add()`, `create()`, or `set()` to create relationships:

```
>>> # The following statements will not work
>>> beatles.members.add(john)
>>> beatles.members.create(name="George Harrison")
>>> beatles.members.set([john, paul, ringo, george])
```

Why? You can't just create a relationship between a `Person` and a `Group` - you need to specify all the detail for the relationship required by the `Membership` model. The simple `add`, `create` and assignment calls don't provide a way to specify this extra detail. As a result, they are disabled for many-to-many relationships that use an intermediate model. The only way to create this type of relationship is to create instances of the intermediate model.

The `remove()` method is disabled for similar reasons. For example, if the custom through table defined by the intermediate model does not enforce uniqueness on the `(model1, model2)` pair, a `remove()` call would not provide enough information as to which intermediate model instance should be deleted:

```
>>> Membership.objects.create(person=ringo, group=beatles,
...     date_joined=date(1968, 9, 4),
...     invite_reason="You've been gone for a month and we miss you.")
>>> beatles.members.all()
<QuerySet [<Person: Ringo Starr>, <Person: Paul McCartney>, <Person: Ringo Starr>]>
>>> # This will not work because it cannot tell which membership to remove
>>> beatles.members.remove(ringo)
```

However, the `clear()` method can be used to remove all many-to-many relationships for an instance:

```
>>> # Beatles have broken up
>>> beatles.members.clear()
>>> # Note that this deletes the intermediate model instances
>>> Membership.objects.all()
<QuerySet []>
```

Once you have established the many-to-many relationships by creating instances of your intermediate model, you can issue queries. Just as with normal many-to-many relationships, you can query using the attributes of the many-to-many-related model:

```
# Find all the groups with a member whose name starts with 'Paul'
>>> Group.objects.filter(members__name__startswith='Paul')
<QuerySet [<Group: The Beatles>]>
```

As you are using an intermediate model, you can also query on its attributes:

```
# Find all the members of the Beatles that joined after 1 Jan 1961
>>> Person.objects.filter(
...     group__name='The Beatles',
...     membership__date_joined__gt=date(1961,1,1))
<QuerySet [ <Person: Ringo Starr > ]>
```

If you need to access a membership’s information you may do so by directly querying the Membership model:

```
>>> ringos_membership = Membership.objects.get(group=beatles, person=ringo)
>>> ringos_membership.date_joined
datetime.date(1962, 8, 16)
>>> ringos_membership.invite_reason
'Needed a new drummer.'
```

Another way to access the same information is by querying the *many-to-many reverse relationship* from a Person object:

```
>>> ringos_membership = ringo.membership_set.get(group=beatles)
>>> ringos_membership.date_joined
datetime.date(1962, 8, 16)
>>> ringos_membership.invite_reason
'Needed a new drummer.'
```

## One-to-one relationships

To define a one-to-one relationship, use *OneToOneField*. You use it just like any other Field type: by including it as a class attribute of your model.

This is most useful on the primary key of an object when that object “extends” another object in some way.

*OneToOneField* requires a positional argument: the class to which the model is related.

For example, if you were building a database of “places”, you would build pretty standard stuff such as address, phone number, etc. in the database. Then, if you wanted to build a database of restaurants on top of the places, instead of repeating yourself and replicating those fields in the Restaurant model, you could make Restaurant have a *OneToOneField* to Place (because a restaurant “is a” place; in fact, to handle this you’d typically use *inheritance*, which involves an implicit one-to-one relation).

As with *ForeignKey*, a *recursive relationship* can be defined and *references to as-yet undefined models* can be made.

### See also:

See the *One-to-one relationship model example* for a full example.

*OneToOneField* fields also accept an optional *parent\_link* argument.

*OneToOneField* classes used to automatically become the primary key on a model. This is no longer true (although you can manually pass in the *primary\_key* argument if you like). Thus, it’s now possible to have multiple fields of type *OneToOneField* on a single model.

## Models across files

It’s perfectly OK to relate a model to one from another app. To do this, import the related model at the top of the file where your model is defined. Then, just refer to the other model class wherever needed. For example:

```

from django.db import models
from geography.models import ZipCode

class Restaurant(models.Model):
    # ...
    zip_code = models.ForeignKey(
        ZipCode,
        on_delete=models.SET_NULL,
        blank=True,
        null=True,
    )

```

## Field name restrictions

Django places only two restrictions on model field names:

1. A field name cannot be a Python reserved word, because that would result in a Python syntax error. For example:

```

class Example(models.Model):
    pass = models.IntegerField() # 'pass' is a reserved word!

```

2. A field name cannot contain more than one underscore in a row, due to the way Django's query lookup syntax works. For example:

```

class Example(models.Model):
    foo__bar = models.IntegerField() # 'foo__bar' has two underscores!

```

These limitations can be worked around, though, because your field name doesn't necessarily have to match your database column name. See the `db_column` option.

SQL reserved words, such as `join`, `where` or `select`, are allowed as model field names, because Django escapes all database table names and column names in every underlying SQL query. It uses the quoting syntax of your particular database engine.

## Custom field types

If one of the existing model fields cannot be used to fit your purposes, or if you wish to take advantage of some less common database column types, you can create your own field class. Full coverage of creating your own fields is provided in *Writing custom model fields*.

## Meta options

Give your model metadata by using an inner class `Meta`, like so:

```

from django.db import models

class Ox(models.Model):
    horn_length = models.IntegerField()

    class Meta:
        ordering = ["horn_length"]
        verbose_name_plural = "oxen"

```

Model metadata is “anything that’s not a field”, such as ordering options (*ordering*), database table name (*db\_table*), or human-readable singular and plural names (*verbose\_name* and *verbose\_name\_plural*). None are required, and adding `class Meta` to a model is completely optional.

A complete list of all possible `Meta` options can be found in the *model option reference*.

## Model attributes

**objects** The most important attribute of a model is the *Manager*. It’s the interface through which database query operations are provided to Django models and is used to *retrieve the instances* from the database. If no custom `Manager` is defined, the default name is *objects*. Managers are only accessible via model classes, not the model instances.

## Model methods

Define custom methods on a model to add custom “row-level” functionality to your objects. Whereas *Manager* methods are intended to do “table-wide” things, model methods should act on a particular model instance.

This is a valuable technique for keeping business logic in one place – the model.

For example, this model has a few custom methods:

```
from django.db import models

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)
    birth_date = models.DateField()

    def baby_boomer_status(self):
        """Returns the person's baby-boomer status."""
        import datetime
        if self.birth_date < datetime.date(1945, 8, 1):
            return "Pre-boomer"
        elif self.birth_date < datetime.date(1965, 1, 1):
            return "Baby boomer"
        else:
            return "Post-boomer"

    def _get_full_name(self):
        """Returns the person's full name."""
        return '%s %s' % (self.first_name, self.last_name)
    full_name = property(_get_full_name)
```

The last method in this example is a *property*.

The *model instance reference* has a complete list of *methods automatically given to each model*. You can override most of these – see *overriding predefined model methods*, below – but there are a couple that you’ll almost always want to define:

**`__str__()` (Python 3)** A Python “magic method” that returns a unicode “representation” of any object. This is what Python and Django will use whenever a model instance needs to be coerced and displayed as a plain string. Most notably, this happens when you display an object in an interactive console or in the admin.

You’ll always want to define this method; the default isn’t very helpful at all.

**`__unicode__()` (Python 2)** Python 2 equivalent of `__str__()`.

`get_absolute_url()` This tells Django how to calculate the URL for an object. Django uses this in its admin interface, and any time it needs to figure out a URL for an object.

Any object that has a URL that uniquely identifies it should define this method.

### Overriding predefined model methods

There's another set of *model methods* that encapsulate a bunch of database behavior that you'll want to customize. In particular you'll often want to change the way `save()` and `delete()` work.

You're free to override these methods (and any other model method) to alter behavior.

A classic use-case for overriding the built-in methods is if you want something to happen whenever you save an object. For example (see `save()` for documentation of the parameters it accepts):

```
from django.db import models

class Blog(models.Model):
    name = models.CharField(max_length=100)
    tagline = models.TextField()

    def save(self, *args, **kwargs):
        do_something()
        super(Blog, self).save(*args, **kwargs) # Call the "real" save() method.
        do_something_else()
```

You can also prevent saving:

```
from django.db import models

class Blog(models.Model):
    name = models.CharField(max_length=100)
    tagline = models.TextField()

    def save(self, *args, **kwargs):
        if self.name == "Yoko Ono's blog":
            return # Yoko shall never have her own blog!
        else:
            super(Blog, self).save(*args, **kwargs) # Call the "real" save() method.
```

It's important to remember to call the superclass method – that's that `super(Blog, self).save(*args, **kwargs)` business – to ensure that the object still gets saved into the database. If you forget to call the superclass method, the default behavior won't happen and the database won't get touched.

It's also important that you pass through the arguments that can be passed to the model method – that's what the `*args, **kwargs` bit does. Django will, from time to time, extend the capabilities of built-in model methods, adding new arguments. If you use `*args, **kwargs` in your method definitions, you are guaranteed that your code will automatically support those arguments when they are added.

---

### Overridden model methods are not called on bulk operations

Note that the `delete()` method for an object is not necessarily called when *deleting objects in bulk using a QuerySet* or as a result of a *cascading delete*. To ensure customized delete logic gets executed, you can use `pre_delete` and/or `post_delete` signals.

Unfortunately, there isn't a workaround when *creating* or *updating* objects in bulk, since none of `save()`, `pre_save`, and `post_save` are called.

---

## Executing custom SQL

Another common pattern is writing custom SQL statements in model methods and module-level methods. For more details on using raw SQL, see the documentation on *using raw SQL*.

## Model inheritance

Model inheritance in Django works almost identically to the way normal class inheritance works in Python, but the basics at the beginning of the page should still be followed. That means the base class should subclass `django.db.models.Model`.

The only decision you have to make is whether you want the parent models to be models in their own right (with their own database tables), or if the parents are just holders of common information that will only be visible through the child models.

There are three styles of inheritance that are possible in Django.

1. Often, you will just want to use the parent class to hold information that you don't want to have to type out for each child model. This class isn't going to ever be used in isolation, so *Abstract base classes* are what you're after.
2. If you're subclassing an existing model (perhaps something from another application entirely) and want each model to have its own database table, *Multi-table inheritance* is the way to go.
3. Finally, if you only want to modify the Python-level behavior of a model, without changing the models fields in any way, you can use *Proxy models*.

## Abstract base classes

Abstract base classes are useful when you want to put some common information into a number of other models. You write your base class and put `abstract=True` in the *Meta* class. This model will then not be used to create any database table. Instead, when it is used as a base class for other models, its fields will be added to those of the child class. It is an error to have fields in the abstract base class with the same name as those in the child (and Django will raise an exception).

An example:

```
from django.db import models

class CommonInfo(models.Model):
    name = models.CharField(max_length=100)
    age = models.PositiveIntegerField()

    class Meta:
        abstract = True

class Student(CommonInfo):
    home_group = models.CharField(max_length=5)
```

The `Student` model will have three fields: `name`, `age` and `home_group`. The `CommonInfo` model cannot be used as a normal Django model, since it is an abstract base class. It does not generate a database table or have a manager, and cannot be instantiated or saved directly.

For many uses, this type of model inheritance will be exactly what you want. It provides a way to factor out common information at the Python level, while still only creating one database table per child model at the database level.

## Meta inheritance

When an abstract base class is created, Django makes any *Meta* inner class you declared in the base class available as an attribute. If a child class does not declare its own *Meta* class, it will inherit the parent's *Meta*. If the child wants to extend the parent's *Meta* class, it can subclass it. For example:

```
from django.db import models

class CommonInfo(models.Model):
    # ...
    class Meta:
        abstract = True
        ordering = ['name']

class Student(CommonInfo):
    # ...
    class Meta(CommonInfo.Meta):
        db_table = 'student_info'
```

Django does make one adjustment to the *Meta* class of an abstract base class: before installing the *Meta* attribute, it sets `abstract=False`. This means that children of abstract base classes don't automatically become abstract classes themselves. Of course, you can make an abstract base class that inherits from another abstract base class. You just need to remember to explicitly set `abstract=True` each time.

Some attributes won't make sense to include in the *Meta* class of an abstract base class. For example, including `db_table` would mean that all the child classes (the ones that don't specify their own *Meta*) would use the same database table, which is almost certainly not what you want.

## Be careful with `related_name` and `related_query_name`

If you are using `related_name` or `related_query_name` on a `ForeignKey` or `ManyToManyField`, you must always specify a *unique* reverse name and query name for the field. This would normally cause a problem in abstract base classes, since the fields on this class are included into each of the child classes, with exactly the same values for the attributes (including `related_name` and `related_query_name`) each time.

To work around this problem, when you are using `related_name` or `related_query_name` in an abstract base class (only), part of the value should contain `'%(app_label)s'` and `'%(class)s'`.

- `'%(class)s'` is replaced by the lower-cased name of the child class that the field is used in.
- `'%(app_label)s'` is replaced by the lower-cased name of the app the child class is contained within. Each installed application name must be unique and the model class names within each app must also be unique, therefore the resulting name will end up being different.

For example, given an app `common/models.py`:

```
from django.db import models

class Base(models.Model):
    m2m = models.ManyToManyField(
        OtherModel,
        related_name="%(app_label)s_%(class)s_related",
        related_query_name="%(app_label)s_%(class)ss",
    )

    class Meta:
        abstract = True
```

```
class ChildA(Base):
    pass

class ChildB(Base):
    pass
```

Along with another app `rare/models.py`:

```
from common.models import Base

class ChildB(Base):
    pass
```

The reverse name of the `common.ChildA.m2m` field will be `common_childa_related` and the reverse query name will be `common_childas`. The reverse name of the `common.ChildB.m2m` field will be `common_childb_related` and the reverse query name will be `common_childbs`. Finally, the reverse name of the `rare.ChildB.m2m` field will be `rare_childb_related` and the reverse query name will be `rare_childbs`. It's up to you how you use the `'%(class)s'` and `'%(app_label)s'` portion to construct your related name or related query name but if you forget to use it, Django will raise errors when you perform system checks (or run `migrate`).

If you don't specify a `related_name` attribute for a field in an abstract base class, the default reverse name will be the name of the child class followed by `'_set'`, just as it normally would be if you'd declared the field directly on the child class. For example, in the above code, if the `related_name` attribute was omitted, the reverse name for the m2m field would be `childa_set` in the `ChildA` case and `childb_set` for the `ChildB` field.

Interpolation of `'%(app_label)s'` and `'%(class)s'` for `related_query_name` was added.

## Multi-table inheritance

The second type of model inheritance supported by Django is when each model in the hierarchy is a model all by itself. Each model corresponds to its own database table and can be queried and created individually. The inheritance relationship introduces links between the child model and each of its parents (via an automatically-created `OneToOneField`). For example:

```
from django.db import models

class Place(models.Model):
    name = models.CharField(max_length=50)
    address = models.CharField(max_length=80)

class Restaurant(Place):
    serves_hot_dogs = models.BooleanField(default=False)
    serves_pizza = models.BooleanField(default=False)
```

All of the fields of `Place` will also be available in `Restaurant`, although the data will reside in a different database table. So these are both possible:

```
>>> Place.objects.filter(name="Bob's Cafe")
>>> Restaurant.objects.filter(name="Bob's Cafe")
```

If you have a `Place` that is also a `Restaurant`, you can get from the `Place` object to the `Restaurant` object by using the lower-case version of the model name:

```
>>> p = Place.objects.get(id=12)
# If p is a Restaurant object, this will give the child class:
>>> p.restaurant
<Restaurant: ...>
```

However, if `p` in the above example was *not* a `Restaurant` (it had been created directly as a `Place` object or was the parent of some other class), referring to `p.restaurant` would raise a `Restaurant.DoesNotExist` exception.

### Meta and multi-table inheritance

In the multi-table inheritance situation, it doesn't make sense for a child class to inherit from its parent's `Meta` class. All the `Meta` options have already been applied to the parent class and applying them again would normally only lead to contradictory behavior (this is in contrast with the abstract base class case, where the base class doesn't exist in its own right).

So a child model does not have access to its parent's `Meta` class. However, there are a few limited cases where the child inherits behavior from the parent: if the child does not specify an `ordering` attribute or a `get_latest_by` attribute, it will inherit these from its parent.

If the parent has an `ordering` and you don't want the child to have any natural ordering, you can explicitly disable it:

```
class ChildModel(ParentModel):
    # ...
    class Meta:
        # Remove parent's ordering effect
        ordering = []
```

### Inheritance and reverse relations

Because multi-table inheritance uses an implicit `OneToOneField` to link the child and the parent, it's possible to move from the parent down to the child, as in the above example. However, this uses up the name that is the default `related_name` value for `ForeignKey` and `ManyToManyField` relations. If you are putting those types of relations on a subclass of the parent model, you **must** specify the `related_name` attribute on each such field. If you forget, Django will raise a validation error.

For example, using the above `Place` class again, let's create another subclass with a `ManyToManyField`:

```
class Supplier(Place):
    customers = models.ManyToManyField(Place)
```

This results in the error:

```
Reverse query name for 'Supplier.customers' clashes with reverse query
name for 'Supplier.place_ptr'.
```

```
HINT: Add or change a related_name argument to the definition for
'Supplier.customers' or 'Supplier.place_ptr'.
```

Adding `related_name` to the `customers` field as follows would resolve the error: `models.ManyToManyField(Place, related_name='provider')`.

## Specifying the parent link field

As mentioned, Django will automatically create a *OneToOneField* linking your child class back to any non-abstract parent models. If you want to control the name of the attribute linking back to the parent, you can create your own *OneToOneField* and set *parent\_link=True* to indicate that your field is the link back to the parent class.

## Proxy models

When using *multi-table inheritance*, a new database table is created for each subclass of a model. This is usually the desired behavior, since the subclass needs a place to store any additional data fields that are not present on the base class. Sometimes, however, you only want to change the Python behavior of a model – perhaps to change the default manager, or add a new method.

This is what proxy model inheritance is for: creating a *proxy* for the original model. You can create, delete and update instances of the proxy model and all the data will be saved as if you were using the original (non-proxied) model. The difference is that you can change things like the default model ordering or the default manager in the proxy, without having to alter the original.

Proxy models are declared like normal models. You tell Django that it's a proxy model by setting the *proxy* attribute of the *Meta* class to *True*.

For example, suppose you want to add a method to the *Person* model. You can do it like this:

```
from django.db import models

class Person(models.Model):
    first_name = models.CharField(max_length=30)
    last_name = models.CharField(max_length=30)

class MyPerson(Person):
    class Meta:
        proxy = True

    def do_something(self):
        # ...
        pass
```

The *MyPerson* class operates on the same database table as its parent *Person* class. In particular, any new instances of *Person* will also be accessible through *MyPerson*, and vice-versa:

```
>>> p = Person.objects.create(first_name="foobar")
>>> MyPerson.objects.get(first_name="foobar")
<MyPerson: foobar>
```

You could also use a proxy model to define a different default ordering on a model. You might not always want to order the *Person* model, but regularly order by the *last\_name* attribute when you use the proxy. This is easy:

```
class OrderedPerson(Person):
    class Meta:
        ordering = ["last_name"]
        proxy = True
```

Now normal *Person* queries will be unordered and *OrderedPerson* queries will be ordered by *last\_name*.

Proxy models inherit *Meta* attributes *in the same way as regular models*.

## QuerySets still return the model that was requested

There is no way to have Django return, say, a `MyPerson` object whenever you query for `Person` objects. A queryset for `Person` objects will return those types of objects. The whole point of proxy objects is that code relying on the original `Person` will use those and your own code can use the extensions you included (that no other code is relying on anyway). It is not a way to replace the `Person` (or any other) model everywhere with something of your own creation.

## Base class restrictions

A proxy model must inherit from exactly one non-abstract model class. You can't inherit from multiple non-abstract models as the proxy model doesn't provide any connection between the rows in the different database tables. A proxy model can inherit from any number of abstract model classes, providing they do *not* define any model fields. A proxy model may also inherit from any number of proxy models that share a common non-abstract parent class.

In earlier versions, a proxy model couldn't inherit more than one proxy model that shared the same parent class.

## Proxy model managers

If you don't specify any model managers on a proxy model, it inherits the managers from its model parents. If you define a manager on the proxy model, it will become the default, although any managers defined on the parent classes will still be available.

Continuing our example from above, you could change the default manager used when you query the `Person` model like this:

```
from django.db import models

class NewManager(models.Manager):
    # ...
    pass

class MyPerson(Person):
    objects = NewManager()

    class Meta:
        proxy = True
```

If you wanted to add a new manager to the Proxy, without replacing the existing default, you can use the techniques described in the [custom manager](#) documentation: create a base class containing the new managers and inherit that after the primary base class:

```
# Create an abstract class for the new manager.
class ExtraManagers(models.Model):
    secondary = NewManager()

    class Meta:
        abstract = True

class MyPerson(Person, ExtraManagers):
    class Meta:
        proxy = True
```

You probably won't need to do this very often, but, when you do, it's possible.

## Differences between proxy inheritance and unmanaged models

Proxy model inheritance might look fairly similar to creating an unmanaged model, using the *managed* attribute on a model's `Meta` class.

With careful setting of `Meta.db_table` you could create an unmanaged model that shadows an existing model and adds Python methods to it. However, that would be very repetitive and fragile as you need to keep both copies synchronized if you make any changes.

On the other hand, proxy models are intended to behave exactly like the model they are proxying for. They are always in sync with the parent model since they directly inherit its fields and managers.

The general rules are:

1. If you are mirroring an existing model or database table and don't want all the original database table columns, use `Meta.managed=False`. That option is normally useful for modeling database views and tables not under the control of Django.
2. If you are wanting to change the Python-only behavior of a model, but keep all the same fields as in the original, use `Meta.proxy=True`. This sets things up so that the proxy model is an exact copy of the storage structure of the original model when data is saved.

## Multiple inheritance

Just as with Python's subclassing, it's possible for a Django model to inherit from multiple parent models. Keep in mind that normal Python name resolution rules apply. The first base class that a particular name (e.g. *Meta*) appears in will be the one that is used; for example, this means that if multiple parents contain a *Meta* class, only the first one is going to be used, and all others will be ignored.

Generally, you won't need to inherit from multiple parents. The main use-case where this is useful is for "mix-in" classes: adding a particular extra field or method to every class that inherits the mix-in. Try to keep your inheritance hierarchies as simple and straightforward as possible so that you won't have to struggle to work out where a particular piece of information is coming from.

Note that inheriting from multiple models that have a common `id` primary key field will raise an error. To properly use multiple inheritance, you can use an explicit *AutoField* in the base models:

```
class Article(models.Model):
    article_id = models.AutoField(primary_key=True)
    ...

class Book(models.Model):
    book_id = models.AutoField(primary_key=True)
    ...

class BookReview(Book, Article):
    pass
```

Or use a common ancestor to hold the *AutoField*:

```
class Piece(models.Model):
    pass

class Article(Piece):
    ...

class Book(Piece):
    ...
```

```
class BookReview(Book, Article):
    pass
```

### Field name “hiding” is not permitted

In normal Python class inheritance, it is permissible for a child class to override any attribute from the parent class. In Django, this isn’t usually permitted for model fields. If a non-abstract model base class has a field called `author`, you can’t create another model field or define an attribute called `author` in any class that inherits from that base class.

This restriction doesn’t apply to model fields inherited from an abstract model. Such fields may be overridden with another field or value, or be removed by setting `field_name = None`.

The ability to override abstract fields was added.

**Warning:** Model managers are inherited from abstract base classes. Overriding an inherited field which is referenced by an inherited *Manager* may cause subtle bugs. See *custom managers and model inheritance*.

**Note:** Some fields define extra attributes on the model, e.g. a *ForeignKey* defines an extra attribute with `_id` appended to the field name, as well as `related_name` and `related_query_name` on the foreign model.

These extra attributes cannot be overridden unless the field that defines it is changed or removed so that it no longer defines the extra attribute.

Overriding fields in a parent model leads to difficulties in areas such as initializing new instances (specifying which field is being initialized in `Model.__init__`) and serialization. These are features which normal Python class inheritance doesn’t have to deal with in quite the same way, so the difference between Django model inheritance and Python class inheritance isn’t arbitrary.

This restriction only applies to attributes which are *Field* instances. Normal Python attributes can be overridden if you wish. It also only applies to the name of the attribute as Python sees it: if you are manually specifying the database column name, you can have the same column name appearing in both a child and an ancestor model for multi-table inheritance (they are columns in two different database tables).

Django will raise a *FieldError* if you override any model field in any ancestor model.

### Organizing models in a package

The `manage.py startapp` command creates an application structure that includes a `models.py` file. If you have many models, organizing them in separate files may be useful.

To do so, create a `models` package. Remove `models.py` and create a `myapp/models/` directory with an `__init__.py` file and the files to store your models. You must import the models in the `__init__.py` file.

For example, if you had `organic.py` and `synthetic.py` in the `models` directory:

```
myapp/models/__init__.py
from .organic import Person
from .synthetic import Robot
```

Explicitly importing each model rather than using `from .models import *` has the advantages of not cluttering the namespace, making code more readable, and keeping code analysis tools useful.

See also:

*The Models Reference* Covers all the model related APIs including model fields, related objects, and `QuerySet`.

## 3.2.2 Making queries

Once you've created your *data models*, Django automatically gives you a database-abstraction API that lets you create, retrieve, update and delete objects. This document explains how to use this API. Refer to the *data model reference* for full details of all the various model lookup options.

Throughout this guide (and in the reference), we'll refer to the following models, which comprise a Weblog application:

```
from django.db import models

class Blog(models.Model):
    name = models.CharField(max_length=100)
    tagline = models.TextField()

    def __str__(self):
        return self.name

class Author(models.Model):
    name = models.CharField(max_length=200)
    email = models.EmailField()

    def __str__(self):
        return self.name

class Entry(models.Model):
    blog = models.ForeignKey(Blog)
    headline = models.CharField(max_length=255)
    body_text = models.TextField()
    pub_date = models.DateField()
    mod_date = models.DateField()
    authors = models.ManyToManyField(Author)
    n_comments = models.IntegerField()
    n_pingbacks = models.IntegerField()
    rating = models.IntegerField()

    def __str__(self):
        return self.headline
```

## Creating objects

To represent database-table data in Python objects, Django uses an intuitive system: A model class represents a database table, and an instance of that class represents a particular record in the database table.

To create an object, instantiate it using keyword arguments to the model class, then call `save()` to save it to the database.

Assuming models live in a file `mysite/blog/models.py`, here's an example:

```
>>> from blog.models import Blog
>>> b = Blog(name='Beatles Blog', tagline='All the latest Beatles news.')
>>> b.save()
```

This performs an `INSERT` SQL statement behind the scenes. Django doesn't hit the database until you explicitly call `save()`.

The `save()` method has no return value.

#### See also:

`save()` takes a number of advanced options not described here. See the documentation for `save()` for complete details.

To create and save an object in a single step, use the `create()` method.

### Saving changes to objects

To save changes to an object that's already in the database, use `save()`.

Given a `Blog` instance `b5` that has already been saved to the database, this example changes its name and updates its record in the database:

```
>>> b5.name = 'New name'
>>> b5.save()
```

This performs an `UPDATE` SQL statement behind the scenes. Django doesn't hit the database until you explicitly call `save()`.

### Saving `ForeignKey` and `ManyToManyField` fields

Updating a `ForeignKey` field works exactly the same way as saving a normal field – simply assign an object of the right type to the field in question. This example updates the `blog` attribute of an `Entry` instance `entry`, assuming appropriate instances of `Entry` and `Blog` are already saved to the database (so we can retrieve them below):

```
>>> from blog.models import Entry
>>> entry = Entry.objects.get(pk=1)
>>> cheese_blog = Blog.objects.get(name="Cheddar Talk")
>>> entry.blog = cheese_blog
>>> entry.save()
```

Updating a `ManyToManyField` works a little differently – use the `add()` method on the field to add a record to the relation. This example adds the `Author` instance `joe` to the `entry` object:

```
>>> from blog.models import Author
>>> joe = Author.objects.create(name="Joe")
>>> entry.authors.add(joe)
```

To add multiple records to a `ManyToManyField` in one go, include multiple arguments in the call to `add()`, like this:

```
>>> john = Author.objects.create(name="John")
>>> paul = Author.objects.create(name="Paul")
>>> george = Author.objects.create(name="George")
>>> ringo = Author.objects.create(name="Ringo")
>>> entry.authors.add(john, paul, george, ringo)
```

Django will complain if you try to assign or add an object of the wrong type.

## Retrieving objects

To retrieve objects from your database, construct a *QuerySet* via a *Manager* on your model class.

A *QuerySet* represents a collection of objects from your database. It can have zero, one or many *filters*. Filters narrow down the query results based on the given parameters. In SQL terms, a *QuerySet* equates to a SELECT statement, and a filter is a limiting clause such as WHERE or LIMIT.

You get a *QuerySet* by using your model's *Manager*. Each model has at least one *Manager*, and it's called *objects* by default. Access it directly via the model class, like so:

```
>>> Blog.objects
<django.db.models.manager.Manager object at ...>
>>> b = Blog(name='Foo', tagline='Bar')
>>> b.objects
Traceback:
...
AttributeError: "Manager isn't accessible via Blog instances."
```

---

**Note:** Managers are accessible only via model classes, rather than from model instances, to enforce a separation between “table-level” operations and “record-level” operations.

---

The *Manager* is the main source of *QuerySets* for a model. For example, `Blog.objects.all()` returns a *QuerySet* that contains all `Blog` objects in the database.

## Retrieving all objects

The simplest way to retrieve objects from a table is to get all of them. To do this, use the `all()` method on a *Manager*:

```
>>> all_entries = Entry.objects.all()
```

The `all()` method returns a *QuerySet* of all the objects in the database.

## Retrieving specific objects with filters

The *QuerySet* returned by `all()` describes all objects in the database table. Usually, though, you'll need to select only a subset of the complete set of objects.

To create such a subset, you refine the initial *QuerySet*, adding filter conditions. The two most common ways to refine a *QuerySet* are:

**filter(\*\*kwargs)** Returns a new *QuerySet* containing objects that match the given lookup parameters.

**exclude(\*\*kwargs)** Returns a new *QuerySet* containing objects that do *not* match the given lookup parameters.

The lookup parameters (`**kwargs` in the above function definitions) should be in the format described in *Field lookups* below.

For example, to get a *QuerySet* of blog entries from the year 2006, use `filter()` like so:

```
Entry.objects.filter(pub_date__year=2006)
```

With the default manager class, it is the same as:

```
Entry.objects.all().filter(pub_date__year=2006)
```

## Chaining filters

The result of refining a *QuerySet* is itself a *QuerySet*, so it's possible to chain refinements together. For example:

```
>>> Entry.objects.filter(
...     headline__startswith='What'
... ).exclude(
...     pub_date__gte=datetime.date.today()
... ).filter(
...     pub_date__gte=datetime(2005, 1, 30)
... )
```

This takes the initial *QuerySet* of all entries in the database, adds a filter, then an exclusion, then another filter. The final result is a *QuerySet* containing all entries with a headline that starts with “What”, that were published between January 30, 2005, and the current day.

## Filtered QuerySets are unique

Each time you refine a *QuerySet*, you get a brand-new *QuerySet* that is in no way bound to the previous *QuerySet*. Each refinement creates a separate and distinct *QuerySet* that can be stored, used and reused.

Example:

```
>>> q1 = Entry.objects.filter(headline__startswith="What")
>>> q2 = q1.exclude(pub_date__gte=datetime.date.today())
>>> q3 = q1.filter(pub_date__gte=datetime.date.today())
```

These three *QuerySets* are separate. The first is a base *QuerySet* containing all entries that contain a headline starting with “What”. The second is a subset of the first, with an additional criteria that excludes records whose `pub_date` is today or in the future. The third is a subset of the first, with an additional criteria that selects only the records whose `pub_date` is today or in the future. The initial *QuerySet* (`q1`) is unaffected by the refinement process.

## QuerySets are lazy

*QuerySets* are lazy – the act of creating a *QuerySet* doesn't involve any database activity. You can stack filters together all day long, and Django won't actually run the query until the *QuerySet* is *evaluated*. Take a look at this example:

```
>>> q = Entry.objects.filter(headline__startswith="What")
>>> q = q.filter(pub_date__lte=datetime.date.today())
>>> q = q.exclude(body_text__icontains="food")
>>> print(q)
```

Though this looks like three database hits, in fact it hits the database only once, at the last line (`print(q)`). In general, the results of a *QuerySet* aren't fetched from the database until you “ask” for them. When you do, the *QuerySet* is *evaluated* by accessing the database. For more details on exactly when evaluation takes place, see *When QuerySets are evaluated*.

## Retrieving a single object with `get ()`

`filter ()` will always give you a `QuerySet`, even if only a single object matches the query - in this case, it will be a `QuerySet` containing a single element.

If you know there is only one object that matches your query, you can use the `get ()` method on a `Manager` which returns the object directly:

```
>>> one_entry = Entry.objects.get(pk=1)
```

You can use any query expression with `get ()`, just like with `filter ()` - again, see *Field lookups* below.

Note that there is a difference between using `get ()`, and using `filter ()` with a slice of `[0]`. If there are no results that match the query, `get ()` will raise a `DoesNotExist` exception. This exception is an attribute of the model class that the query is being performed on - so in the code above, if there is no `Entry` object with a primary key of 1, Django will raise `Entry.DoesNotExist`.

Similarly, Django will complain if more than one item matches the `get ()` query. In this case, it will raise `MultipleObjectsReturned`, which again is an attribute of the model class itself.

## Other `QuerySet` methods

Most of the time you'll use `all ()`, `get ()`, `filter ()` and `exclude ()` when you need to look up objects from the database. However, that's far from all there is; see the *QuerySet API Reference* for a complete list of all the various `QuerySet` methods.

## Limiting `QuerySets`

Use a subset of Python's array-slicing syntax to limit your `QuerySet` to a certain number of results. This is the equivalent of SQL's `LIMIT` and `OFFSET` clauses.

For example, this returns the first 5 objects (`LIMIT 5`):

```
>>> Entry.objects.all()[:5]
```

This returns the sixth through tenth objects (`OFFSET 5 LIMIT 5`):

```
>>> Entry.objects.all()[5:10]
```

Negative indexing (i.e. `Entry.objects.all()[-1]`) is not supported.

Generally, slicing a `QuerySet` returns a new `QuerySet` - it doesn't evaluate the query. An exception is if you use the "step" parameter of Python slice syntax. For example, this would actually execute the query in order to return a list of every *second* object of the first 10:

```
>>> Entry.objects.all()[0:10:2]
```

To retrieve a *single* object rather than a list (e.g. `SELECT foo FROM bar LIMIT 1`), use a simple index instead of a slice. For example, this returns the first `Entry` in the database, after ordering entries alphabetically by headline:

```
>>> Entry.objects.order_by('headline')[0]
```

This is roughly equivalent to:

```
>>> Entry.objects.order_by('headline')[0:1].get()
```

Note, however, that the first of these will raise `IndexError` while the second will raise `DoesNotExist` if no objects match the given criteria. See `get()` for more details.

## Field lookups

Field lookups are how you specify the meat of an SQL `WHERE` clause. They're specified as keyword arguments to the `QuerySet` methods `filter()`, `exclude()` and `get()`.

Basic lookups keyword arguments take the form `field__lookuptype=value`. (That's a double-underscore). For example:

```
>>> Entry.objects.filter(pub_date__lte='2006-01-01')
```

translates (roughly) into the following SQL:

```
SELECT * FROM blog_entry WHERE pub_date <= '2006-01-01';
```

### How this is possible

Python has the ability to define functions that accept arbitrary name-value arguments whose names and values are evaluated at runtime. For more information, see [Keyword Arguments](#) in the official Python tutorial.

The field specified in a lookup has to be the name of a model field. There's one exception though, in case of a `ForeignKey` you can specify the field name suffixed with `_id`. In this case, the value parameter is expected to contain the raw value of the foreign model's primary key. For example:

```
>>> Entry.objects.filter(blog_id=4)
```

If you pass an invalid keyword argument, a lookup function will raise `TypeError`.

The database API supports about two dozen lookup types; a complete reference can be found in the [field lookup reference](#). To give you a taste of what's available, here's some of the more common lookups you'll probably use:

**exact** An "exact" match. For example:

```
>>> Entry.objects.get(headline__exact="Cat bites dog")
```

Would generate SQL along these lines:

```
SELECT ... WHERE headline = 'Cat bites dog';
```

If you don't provide a lookup type – that is, if your keyword argument doesn't contain a double underscore – the lookup type is assumed to be `exact`.

For example, the following two statements are equivalent:

```
>>> Blog.objects.get(id__exact=14) # Explicit form
>>> Blog.objects.get(id=14)       # __exact is implied
```

This is for convenience, because `exact` lookups are the common case.

**icontains** A case-insensitive match. So, the query:

```
>>> Blog.objects.get(name__icontains="beatles blog")
```

Would match a `Blog` titled "Beatles Blog", "beatles blog", or even "BeAtLEs bLoG".

**contains** Case-sensitive containment test. For example:

```
Entry.objects.get(headline__contains='Lennon')
```

Roughly translates to this SQL:

```
SELECT ... WHERE headline LIKE '%Lennon%';
```

Note this will match the headline 'Today Lennon honored' but not 'today lennon honored'.

There's also a case-insensitive version, *icontains*.

**startswith, endswith** Starts-with and ends-with search, respectively. There are also case-insensitive versions called *istartswith* and *iendswith*.

Again, this only scratches the surface. A complete reference can be found in the *field lookup reference*.

## Lookups that span relationships

Django offers a powerful and intuitive way to “follow” relationships in lookups, taking care of the SQL JOINS for you automatically, behind the scenes. To span a relationship, just use the field name of related fields across models, separated by double underscores, until you get to the field you want.

This example retrieves all `Entry` objects with a `Blog` whose name is 'Beatles Blog':

```
>>> Entry.objects.filter(blog__name='Beatles Blog')
```

This spanning can be as deep as you'd like.

It works backwards, too. To refer to a “reverse” relationship, just use the lowercase name of the model.

This example retrieves all `Blog` objects which have at least one `Entry` whose headline contains 'Lennon':

```
>>> Blog.objects.filter(entry__headline__contains='Lennon')
```

If you are filtering across multiple relationships and one of the intermediate models doesn't have a value that meets the filter condition, Django will treat it as if there is an empty (all values are NULL), but valid, object there. All this means is that no error will be raised. For example, in this filter:

```
Blog.objects.filter(entry__authors__name='Lennon')
```

(if there was a related `Author` model), if there was no `author` associated with an `entry`, it would be treated as if there was also no name attached, rather than raising an error because of the missing `author`. Usually this is exactly what you want to have happen. The only case where it might be confusing is if you are using *isnull*. Thus:

```
Blog.objects.filter(entry__authors__name__isnull=True)
```

will return `Blog` objects that have an empty name on the `author` and also those which have an empty `author` on the `entry`. If you don't want those latter objects, you could write:

```
Blog.objects.filter(entry__authors__isnull=False, entry__authors__name__isnull=True)
```

## Spanning multi-valued relationships

When you are filtering an object based on a *ManyToManyField* or a reverse *ForeignKey*, there are two different sorts of filter you may be interested in. Consider the `Blog/Entry` relationship (`Blog` to `Entry` is a one-to-many

relation). We might be interested in finding blogs that have an entry which has both “Lennon” in the headline and was published in 2008. Or we might want to find blogs that have an entry with “Lennon” in the headline as well as an entry that was published in 2008. Since there are multiple entries associated with a single `Blog`, both of these queries are possible and make sense in some situations.

The same type of situation arises with a `ManyToManyField`. For example, if an `Entry` has a `ManyToManyField` called `tags`, we might want to find entries linked to tags called “music” and “bands” or we might want an entry that contains a tag with a name of “music” and a status of “public”.

To handle both of these situations, Django has a consistent way of processing `filter()` calls. Everything inside a single `filter()` call is applied simultaneously to filter out items matching all those requirements. Successive `filter()` calls further restrict the set of objects, but for multi-valued relations, they apply to any object linked to the primary model, not necessarily those objects that were selected by an earlier `filter()` call.

That may sound a bit confusing, so hopefully an example will clarify. To select all blogs that contain entries with both “Lennon” in the headline and that were published in 2008 (the same entry satisfying both conditions), we would write:

```
Blog.objects.filter(entry__headline__contains='Lennon', entry__pub_date__year=2008)
```

To select all blogs that contain an entry with “Lennon” in the headline **as well as** an entry that was published in 2008, we would write:

```
Blog.objects.filter(entry__headline__contains='Lennon').filter(entry__pub_date__
↳year=2008)
```

Suppose there is only one blog that had both entries containing “Lennon” and entries from 2008, but that none of the entries from 2008 contained “Lennon”. The first query would not return any blogs, but the second query would return that one blog.

In the second example, the first filter restricts the queryset to all those blogs linked to entries with “Lennon” in the headline. The second filter restricts the set of blogs *further* to those that are also linked to entries that were published in 2008. The entries selected by the second filter may or may not be the same as the entries in the first filter. We are filtering the `Blog` items with each filter statement, not the `Entry` items.

**Note:** The behavior of `filter()` for queries that span multi-value relationships, as described above, is not implemented equivalently for `exclude()`. Instead, the conditions in a single `exclude()` call will not necessarily refer to the same item.

For example, the following query would exclude blogs that contain *both* entries with “Lennon” in the headline *and* entries published in 2008:

```
Blog.objects.exclude(
    entry__headline__contains='Lennon',
    entry__pub_date__year=2008,
)
```

However, unlike the behavior when using `filter()`, this will not limit blogs based on entries that satisfy both conditions. In order to do that, i.e. to select all blogs that do not contain entries published with “Lennon” that were published in 2008, you need to make two queries:

```
Blog.objects.exclude(
    entry__in=Entry.objects.filter(
        headline__contains='Lennon',
        pub_date__year=2008,
    ),
)
```

## Filters can reference fields on the model

In the examples given so far, we have constructed filters that compare the value of a model field with a constant. But what if you want to compare the value of a model field with another field on the same model?

Django provides *F expressions* to allow such comparisons. Instances of `F()` act as a reference to a model field within a query. These references can then be used in query filters to compare the values of two different fields on the same model instance.

For example, to find a list of all blog entries that have had more comments than pingbacks, we construct an `F()` object to reference the pingback count, and use that `F()` object in the query:

```
>>> from django.db.models import F
>>> Entry.objects.filter(n_comments__gt=F('n_pingbacks'))
```

Django supports the use of addition, subtraction, multiplication, division, modulo, and power arithmetic with `F()` objects, both with constants and with other `F()` objects. To find all the blog entries with more than *twice* as many comments as pingbacks, we modify the query:

```
>>> Entry.objects.filter(n_comments__gt=F('n_pingbacks') * 2)
```

To find all the entries where the rating of the entry is less than the sum of the pingback count and comment count, we would issue the query:

```
>>> Entry.objects.filter(rating__lt=F('n_comments') + F('n_pingbacks'))
```

You can also use the double underscore notation to span relationships in an `F()` object. An `F()` object with a double underscore will introduce any joins needed to access the related object. For example, to retrieve all the entries where the author's name is the same as the blog name, we could issue the query:

```
>>> Entry.objects.filter(authors__name=F('blog__name'))
```

For date and date/time fields, you can add or subtract a `timedelta` object. The following would return all entries that were modified more than 3 days after they were published:

```
>>> from datetime import timedelta
>>> Entry.objects.filter(mod_date__gt=F('pub_date') + timedelta(days=3))
```

The `F()` objects support bitwise operations by `.bitand()` and `.bitor()`, for example:

```
>>> F('somefield').bitand(16)
```

## The pk lookup shortcut

For convenience, Django provides a `pk` lookup shortcut, which stands for “primary key”.

In the example `Blog` model, the primary key is the `id` field, so these three statements are equivalent:

```
>>> Blog.objects.get(id__exact=14) # Explicit form
>>> Blog.objects.get(id=14) # __exact is implied
>>> Blog.objects.get(pk=14) # pk implies id__exact
```

The use of `pk` isn't limited to `__exact` queries – any query term can be combined with `pk` to perform a query on the primary key of a model:

```
# Get blogs entries with id 1, 4 and 7
>>> Blog.objects.filter(pk__in=[1,4,7])

# Get all blog entries with id > 14
>>> Blog.objects.filter(pk__gt=14)
```

pk lookups also work across joins. For example, these three statements are equivalent:

```
>>> Entry.objects.filter(blog__id__exact=3) # Explicit form
>>> Entry.objects.filter(blog__id=3)       # __exact is implied
>>> Entry.objects.filter(blog__pk=3)       # __pk implies __id__exact
```

## Escaping percent signs and underscores in LIKE statements

The field lookups that equate to LIKE SQL statements (`iexact`, `contains`, `icontains`, `startswith`, `istartswith`, `endswith` and `iendswith`) will automatically escape the two special characters used in LIKE statements – the percent sign and the underscore. (In a LIKE statement, the percent sign signifies a multiple-character wildcard and the underscore signifies a single-character wildcard.)

This means things should work intuitively, so the abstraction doesn't leak. For example, to retrieve all the entries that contain a percent sign, just use the percent sign as any other character:

```
>>> Entry.objects.filter(headline__contains='%')
```

Django takes care of the quoting for you; the resulting SQL will look something like this:

```
SELECT ... WHERE headline LIKE '%\%%';
```

Same goes for underscores. Both percentage signs and underscores are handled for you transparently.

## Caching and QuerySets

Each *QuerySet* contains a cache to minimize database access. Understanding how it works will allow you to write the most efficient code.

In a newly created *QuerySet*, the cache is empty. The first time a *QuerySet* is evaluated – and, hence, a database query happens – Django saves the query results in the *QuerySet*'s cache and returns the results that have been explicitly requested (e.g., the next element, if the *QuerySet* is being iterated over). Subsequent evaluations of the *QuerySet* reuse the cached results.

Keep this caching behavior in mind, because it may bite you if you don't use your *QuerySets* correctly. For example, the following will create two *QuerySets*, evaluate them, and throw them away:

```
>>> print([e.headline for e in Entry.objects.all()])
>>> print([e.pub_date for e in Entry.objects.all()])
```

That means the same database query will be executed twice, effectively doubling your database load. Also, there's a possibility the two lists may not include the same database records, because an *Entry* may have been added or deleted in the split second between the two requests.

To avoid this problem, simply save the *QuerySet* and reuse it:

```
>>> queryset = Entry.objects.all()
>>> print([p.headline for p in queryset]) # Evaluate the query set.
>>> print([p.pub_date for p in queryset]) # Re-use the cache from the evaluation.
```

## When querySets are not cached

Querysets do not always cache their results. When evaluating only *part* of the queryset, the cache is checked, but if it is not populated then the items returned by the subsequent query are not cached. Specifically, this means that *limiting the queryset* using an array slice or an index will not populate the cache.

For example, repeatedly getting a certain index in a queryset object will query the database each time:

```
>>> queryset = Entry.objects.all()
>>> print(queryset[5]) # Queries the database
>>> print(queryset[5]) # Queries the database again
```

However, if the entire queryset has already been evaluated, the cache will be checked instead:

```
>>> queryset = Entry.objects.all()
>>> [entry for entry in queryset] # Queries the database
>>> print(queryset[5]) # Uses cache
>>> print(queryset[5]) # Uses cache
```

Here are some examples of other actions that will result in the entire queryset being evaluated and therefore populate the cache:

```
>>> [entry for entry in queryset]
>>> bool(queryset)
>>> entry in queryset
>>> list(queryset)
```

---

**Note:** Simply printing the queryset will not populate the cache. This is because the call to `__repr__()` only returns a slice of the entire queryset.

---

## Complex lookups with Q objects

Keyword argument queries – in `filter()`, etc. – are “AND”ed together. If you need to execute more complex queries (for example, queries with OR statements), you can use *Q objects*.

A *Q object* (`django.db.models.Q`) is an object used to encapsulate a collection of keyword arguments. These keyword arguments are specified as in “Field lookups” above.

For example, this Q object encapsulates a single LIKE query:

```
from django.db.models import Q
Q(question__startswith='What')
```

Q objects can be combined using the `&` and `|` operators. When an operator is used on two Q objects, it yields a new Q object.

For example, this statement yields a single Q object that represents the “OR” of two “question\_\_startswith” queries:

```
Q(question__startswith='Who') | Q(question__startswith='What')
```

This is equivalent to the following SQL WHERE clause:

```
WHERE question LIKE 'Who%' OR question LIKE 'What%'
```

You can compose statements of arbitrary complexity by combining `Q` objects with the `&` and `|` operators and use parenthetical grouping. Also, `Q` objects can be negated using the `~` operator, allowing for combined lookups that combine both a normal query and a negated (NOT) query:

```
Q(question__startswith='Who') | ~Q(pub_date__year=2005)
```

Each lookup function that takes keyword-arguments (e.g. `filter()`, `exclude()`, `get()`) can also be passed one or more `Q` objects as positional (not-named) arguments. If you provide multiple `Q` object arguments to a lookup function, the arguments will be “AND”ed together. For example:

```
Poll.objects.get(
    Q(question__startswith='Who'),
    Q(pub_date=date(2005, 5, 2)) | Q(pub_date=date(2005, 5, 6))
)
```

... roughly translates into the SQL:

```
SELECT * from polls WHERE question LIKE 'Who%'
AND (pub_date = '2005-05-02' OR pub_date = '2005-05-06')
```

Lookup functions can mix the use of `Q` objects and keyword arguments. All arguments provided to a lookup function (be they keyword arguments or `Q` objects) are “AND”ed together. However, if a `Q` object is provided, it must precede the definition of any keyword arguments. For example:

```
Poll.objects.get(
    Q(pub_date=date(2005, 5, 2)) | Q(pub_date=date(2005, 5, 6)),
    question__startswith='Who',
)
```

... would be a valid query, equivalent to the previous example; but:

```
# INVALID QUERY
Poll.objects.get(
    question__startswith='Who',
    Q(pub_date=date(2005, 5, 2)) | Q(pub_date=date(2005, 5, 6))
)
```

... would not be valid.

### See also:

The [OR lookups examples](#) in the Django unit tests show some possible uses of `Q`.

## Comparing objects

To compare two model instances, just use the standard Python comparison operator, the double equals sign: `==`. Behind the scenes, that compares the primary key values of two models.

Using the `Entry` example above, the following two statements are equivalent:

```
>>> some_entry == other_entry
>>> some_entry.id == other_entry.id
```

If a model’s primary key isn’t called `id`, no problem. Comparisons will always use the primary key, whatever it’s called. For example, if a model’s primary key field is called `name`, these two statements are equivalent:

```
>>> some_obj == other_obj
>>> some_obj.name == other_obj.name
```

## Deleting objects

The delete method, conveniently, is named `delete()`. This method immediately deletes the object and returns the number of objects deleted and a dictionary with the number of deletions per object type. Example:

```
>>> e.delete()
(1, {'weblog.Entry': 1})
```

The return value describing the number of objects deleted was added.

You can also delete objects in bulk. Every `QuerySet` has a `delete()` method, which deletes all members of that `QuerySet`.

For example, this deletes all `Entry` objects with a `pub_date` year of 2005:

```
>>> Entry.objects.filter(pub_date__year=2005).delete()
(5, {'webapp.Entry': 5})
```

Keep in mind that this will, whenever possible, be executed purely in SQL, and so the `delete()` methods of individual object instances will not necessarily be called during the process. If you've provided a custom `delete()` method on a model class and want to ensure that it is called, you will need to “manually” delete instances of that model (e.g., by iterating over a `QuerySet` and calling `delete()` on each object individually) rather than using the bulk `delete()` method of a `QuerySet`.

The return value describing the number of objects deleted was added.

When Django deletes an object, by default it emulates the behavior of the SQL constraint `ON DELETE CASCADE` – in other words, any objects which had foreign keys pointing at the object to be deleted will be deleted along with it. For example:

```
b = Blog.objects.get(pk=1)
# This will delete the Blog and all of its Entry objects.
b.delete()
```

This cascade behavior is customizable via the `on_delete` argument to the `ForeignKey`.

Note that `delete()` is the only `QuerySet` method that is not exposed on a `Manager` itself. This is a safety mechanism to prevent you from accidentally requesting `Entry.objects.delete()`, and deleting *all* the entries. If you *do* want to delete all the objects, then you have to explicitly request a complete query set:

```
Entry.objects.all().delete()
```

## Copying model instances

Although there is no built-in method for copying model instances, it is possible to easily create new instance with all fields' values copied. In the simplest case, you can just set `pk` to `None`. Using our blog example:

```
blog = Blog(name='My blog', tagline=' Blogging is easy')
blog.save() # blog.pk == 1

blog.pk = None
blog.save() # blog.pk == 2
```

Things get more complicated if you use inheritance. Consider a subclass of `Blog`:

```
class ThemeBlog(Blog):
    theme = models.CharField(max_length=200)
```

```
django_blog = ThemeBlog(name='Django', tagline='Django is easy', theme='python')
django_blog.save() # django_blog.pk == 3
```

Due to how inheritance works, you have to set both `pk` and `id` to `None`:

```
django_blog.pk = None
django_blog.id = None
django_blog.save() # django_blog.pk == 4
```

This process doesn't copy relations that aren't part of the model's database table. For example, `Entry` has a `ManyToManyField` to `Author`. After duplicating an entry, you must set the many-to-many relations for the new entry:

```
entry = Entry.objects.all()[0] # some previous entry
old_authors = entry.authors.all()
entry.pk = None
entry.save()
entry.authors.set(old_authors)
```

For a `OneToOneField`, you must duplicate the related object and assign it to the new object's field to avoid violating the one-to-one unique constraint. For example, assuming `entry` is already duplicated as above:

```
detail = EntryDetail.objects.all()[0]
detail.pk = None
detail.entry = entry
detail.save()
```

## Updating multiple objects at once

Sometimes you want to set a field to a particular value for all the objects in a `QuerySet`. You can do this with the `update()` method. For example:

```
# Update all the headlines with pub_date in 2007.
Entry.objects.filter(pub_date__year=2007).update(headline='Everything is the same')
```

You can only set non-relation fields and `ForeignKey` fields using this method. To update a non-relation field, provide the new value as a constant. To update `ForeignKey` fields, set the new value to be the new model instance you want to point to. For example:

```
>>> b = Blog.objects.get(pk=1)

# Change every Entry so that it belongs to this Blog.
>>> Entry.objects.all().update(blog=b)
```

The `update()` method is applied instantly and returns the number of rows matched by the query (which may not be equal to the number of rows updated if some rows already have the new value). The only restriction on the `QuerySet` being updated is that it can only access one database table: the model's main table. You can filter based on related fields, but you can only update columns in the model's main table. Example:

```
>>> b = Blog.objects.get(pk=1)

# Update all the headlines belonging to this Blog.
>>> Entry.objects.select_related().filter(blog=b).update(headline='Everything is the_
↳ same')
```

Be aware that the `update()` method is converted directly to an SQL statement. It is a bulk operation for direct updates. It doesn't run any `save()` methods on your models, or emit the `pre_save` or `post_save` signals (which are a consequence of calling `save()`), or honor the `auto_now` field option. If you want to save every item in a `QuerySet` and make sure that the `save()` method is called on each instance, you don't need any special function to handle that. Just loop over them and call `save()`:

```
for item in my_queryset:
    item.save()
```

Calls to update can also use `F expressions` to update one field based on the value of another field in the model. This is especially useful for incrementing counters based upon their current value. For example, to increment the pingback count for every entry in the blog:

```
>>> Entry.objects.all().update(n_pingbacks=F('n_pingbacks') + 1)
```

However, unlike `F()` objects in filter and exclude clauses, you can't introduce joins when you use `F()` objects in an update – you can only reference fields local to the model being updated. If you attempt to introduce a join with an `F()` object, a `FieldError` will be raised:

```
# This will raise a FieldError
>>> Entry.objects.update(headline=F('blog__name'))
```

## Related objects

When you define a relationship in a model (i.e., a `ForeignKey`, `OneToOneField`, or `ManyToManyField`), instances of that model will have a convenient API to access the related object(s).

Using the models at the top of this page, for example, an `Entry` object `e` can get its associated `Blog` object by accessing the `blog` attribute: `e.blog`.

(Behind the scenes, this functionality is implemented by Python `descriptors`. This shouldn't really matter to you, but we point it out here for the curious.)

Django also creates API accessors for the “other” side of the relationship – the link from the related model to the model that defines the relationship. For example, a `Blog` object `b` has access to a list of all related `Entry` objects via the `entry_set` attribute: `b.entry_set.all()`.

All examples in this section use the sample `Blog`, `Author` and `Entry` models defined at the top of this page.

## One-to-many relationships

### Forward

If a model has a `ForeignKey`, instances of that model will have access to the related (foreign) object via a simple attribute of the model.

Example:

```
>>> e = Entry.objects.get(id=2)
>>> e.blog # Returns the related Blog object.
```

You can get and set via a foreign-key attribute. As you may expect, changes to the foreign key aren't saved to the database until you call `save()`. Example:

```
>>> e = Entry.objects.get(id=2)
>>> e.blog = some_blog
>>> e.save()
```

If a `ForeignKey` field has `null=True` set (i.e., it allows NULL values), you can assign `None` to remove the relation. Example:

```
>>> e = Entry.objects.get(id=2)
>>> e.blog = None
>>> e.save() # "UPDATE blog_entry SET blog_id = NULL ...;"
```

Forward access to one-to-many relationships is cached the first time the related object is accessed. Subsequent accesses to the foreign key on the same object instance are cached. Example:

```
>>> e = Entry.objects.get(id=2)
>>> print(e.blog) # Hits the database to retrieve the associated Blog.
>>> print(e.blog) # Doesn't hit the database; uses cached version.
```

Note that the `select_related()` `QuerySet` method recursively prepopulates the cache of all one-to-many relationships ahead of time. Example:

```
>>> e = Entry.objects.select_related().get(id=2)
>>> print(e.blog) # Doesn't hit the database; uses cached version.
>>> print(e.blog) # Doesn't hit the database; uses cached version.
```

### Following relationships “backward”

If a model has a `ForeignKey`, instances of the foreign-key model will have access to a `Manager` that returns all instances of the first model. By default, this `Manager` is named `FOO_set`, where `FOO` is the source model name, lowercased. This `Manager` returns `QuerySets`, which can be filtered and manipulated as described in the “Retrieving objects” section above.

Example:

```
>>> b = Blog.objects.get(id=1)
>>> b.entry_set.all() # Returns all Entry objects related to Blog.

# b.entry_set is a Manager that returns QuerySets.
>>> b.entry_set.filter(headline__contains='Lennon')
>>> b.entry_set.count()
```

You can override the `FOO_set` name by setting the `related_name` parameter in the `ForeignKey` definition. For example, if the `Entry` model was altered to `blog = ForeignKey(Blog, on_delete=models.CASCADE, related_name='entries')`, the above example code would look like this:

```
>>> b = Blog.objects.get(id=1)
>>> b.entries.all() # Returns all Entry objects related to Blog.

# b.entries is a Manager that returns QuerySets.
>>> b.entries.filter(headline__contains='Lennon')
>>> b.entries.count()
```

## Using a custom reverse manager

By default the *RelatedManager* used for reverse relations is a subclass of the *default manager* for that model. If you would like to specify a different manager for a given query you can use the following syntax:

```
from django.db import models

class Entry(models.Model):
    #...
    objects = models.Manager() # Default Manager
    entries = EntryManager() # Custom Manager

b = Blog.objects.get(id=1)
b.entry_set(manager='entries').all()
```

If `EntryManager` performed default filtering in its `get_queryset()` method, that filtering would apply to the `all()` call.

Of course, specifying a custom reverse manager also enables you to call its custom methods:

```
b.entry_set(manager='entries').is_published()
```

## Additional methods to handle related objects

In addition to the *QuerySet* methods defined in “Retrieving objects” above, the *ForeignKey Manager* has additional methods used to handle the set of related objects. A synopsis of each is below, and complete details can be found in the *related objects reference*.

**add(obj1, obj2, ...)** Adds the specified model objects to the related object set.

**create(\*\*kwargs)** Creates a new object, saves it and puts it in the related object set. Returns the newly created object.

**remove(obj1, obj2, ...)** Removes the specified model objects from the related object set.

**clear()** Removes all objects from the related object set.

**set(objs)** Replace the set of related objects.

To assign the members of a related set, use the `set()` method with an iterable of object instances or a list of primary key values. For example:

```
b = Blog.objects.get(id=1)
b.entry_set.set([e1, e2])
```

In this example, `e1` and `e2` can be full `Entry` instances, or integer primary key values.

If the `clear()` method is available, any pre-existing objects will be removed from the `entry_set` before all objects in the iterable (in this case, a list) are added to the set. If the `clear()` method is *not* available, all objects in the iterable will be added without removing any existing elements.

Each “reverse” operation described in this section has an immediate effect on the database. Every addition, creation and deletion is immediately and automatically saved to the database.

## Many-to-many relationships

Both ends of a many-to-many relationship get automatic API access to the other end. The API works just as a “backward” one-to-many relationship, above.

The only difference is in the attribute naming: The model that defines the *ManyToManyField* uses the attribute name of that field itself, whereas the “reverse” model uses the lowercased model name of the original model, plus `'_set'` (just like reverse one-to-many relationships).

An example makes this easier to understand:

```
e = Entry.objects.get(id=3)
e.authors.all() # Returns all Author objects for this Entry.
e.authors.count()
e.authors.filter(name__contains='John')

a = Author.objects.get(id=5)
a.entry_set.all() # Returns all Entry objects for this Author.
```

Like *ForeignKey*, *ManyToManyField* can specify `related_name`. In the above example, if the *ManyToManyField* in *Entry* had specified `related_name='entries'`, then each *Author* instance would have an `entries` attribute instead of `entry_set`.

## One-to-one relationships

One-to-one relationships are very similar to many-to-one relationships. If you define a *OneToOneField* on your model, instances of that model will have access to the related object via a simple attribute of the model.

For example:

```
class EntryDetail(models.Model):
    entry = models.OneToOneField(Entry, on_delete=models.CASCADE)
    details = models.TextField()

ed = EntryDetail.objects.get(id=2)
ed.entry # Returns the related Entry object.
```

The difference comes in “reverse” queries. The related model in a one-to-one relationship also has access to a *Manager* object, but that *Manager* represents a single object, rather than a collection of objects:

```
e = Entry.objects.get(id=2)
e.entrydetail # returns the related EntryDetail object
```

If no object has been assigned to this relationship, Django will raise a `DoesNotExist` exception.

Instances can be assigned to the reverse relationship in the same way as you would assign the forward relationship:

```
e.entrydetail = ed
```

## How are the backward relationships possible?

Other object-relational mappers require you to define relationships on both sides. The Django developers believe this is a violation of the DRY (Don’t Repeat Yourself) principle, so Django only requires you to define the relationship on one end.

But how is this possible, given that a model class doesn't know which other model classes are related to it until those other model classes are loaded?

The answer lies in the *app registry*. When Django starts, it imports each application listed in *INSTALLED\_APPS*, and then the `models` module inside each application. Whenever a new model class is created, Django adds backward-relationships to any related models. If the related models haven't been imported yet, Django keeps tracks of the relationships and adds them when the related models eventually are imported.

For this reason, it's particularly important that all the models you're using be defined in applications listed in *INSTALLED\_APPS*. Otherwise, backwards relations may not work properly.

## Queries over related objects

Queries involving related objects follow the same rules as queries involving normal value fields. When specifying the value for a query to match, you may use either an object instance itself, or the primary key value for the object.

For example, if you have a `Blog` object `b` with `id=5`, the following three queries would be identical:

```
Entry.objects.filter(blog=b) # Query using object instance
Entry.objects.filter(blog=b.id) # Query using id from instance
Entry.objects.filter(blog=5) # Query using id directly
```

## Falling back to raw SQL

If you find yourself needing to write an SQL query that is too complex for Django's database-mapper to handle, you can fall back on writing SQL by hand. Django has a couple of options for writing raw SQL queries; see *Performing raw SQL queries*.

Finally, it's important to note that the Django database layer is merely an interface to your database. You can access your database via other tools, programming languages or database frameworks; there's nothing Django-specific about your database.

## 3.2.3 Aggregation

The topic guide on *Django's database-abstraction API* described the way that you can use Django queries that create, retrieve, update and delete individual objects. However, sometimes you will need to retrieve values that are derived by summarizing or *aggregating* a collection of objects. This topic guide describes the ways that aggregate values can be generated and returned using Django queries.

Throughout this guide, we'll refer to the following models. These models are used to track the inventory for a series of online bookstores:

```
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=100)
    age = models.IntegerField()

class Publisher(models.Model):
    name = models.CharField(max_length=300)
    num_awards = models.IntegerField()

class Book(models.Model):
    name = models.CharField(max_length=300)
    pages = models.IntegerField()
```

```

price = models.DecimalField(max_digits=10, decimal_places=2)
rating = models.FloatField()
authors = models.ManyToManyField(Author)
publisher = models.ForeignKey(Publisher)
pubdate = models.DateField()

```

```

class Store(models.Model):
    name = models.CharField(max_length=300)
    books = models.ManyToManyField(Book)
    registered_users = models.PositiveIntegerField()

```

## Cheat sheet

In a hurry? Here's how to do common aggregate queries, assuming the models above:

```

# Total number of books.
>>> Book.objects.count()
2452

# Total number of books with publisher=BaloneyPress
>>> Book.objects.filter(publisher__name='BaloneyPress').count()
73

# Average price across all books.
>>> from django.db.models import Avg
>>> Book.objects.all().aggregate(Avg('price'))
{'price__avg': 34.35}

# Max price across all books.
>>> from django.db.models import Max
>>> Book.objects.all().aggregate(Max('price'))
{'price__max': Decimal('81.20')}

# Cost per page
>>> from django.db.models import F, FloatField, Sum
>>> Book.objects.all().aggregate(
...     price_per_page=Sum(F('price')/F('pages'), output_field=FloatField())
)
{'price_per_page': 0.4470664529184653}

# All the following queries involve traversing the Book<->Publisher
# foreign key relationship backwards.

# Each publisher, each with a count of books as a "num_books" attribute.
>>> from django.db.models import Count
>>> pubs = Publisher.objects.annotate(num_books=Count('book'))
>>> pubs
<QuerySet [ <Publisher: BaloneyPress>, <Publisher: SalamiPress>, ...]>
>>> pubs[0].num_books
73

# The top 5 publishers, in order by number of books.
>>> pubs = Publisher.objects.annotate(num_books=Count('book')).order_by('-num_books
↵')[ :5]
>>> pubs[0].num_books
1323

```

## Generating aggregates over a `QuerySet`

Django provides two ways to generate aggregates. The first way is to generate summary values over an entire `QuerySet`. For example, say you wanted to calculate the average price of all books available for sale. Django's query syntax provides a means for describing the set of all books:

```
>>> Book.objects.all()
```

What we need is a way to calculate summary values over the objects that belong to this `QuerySet`. This is done by appending an `aggregate()` clause onto the `QuerySet`:

```
>>> from django.db.models import Avg
>>> Book.objects.all().aggregate(Avg('price'))
{'price__avg': 34.35}
```

The `all()` is redundant in this example, so this could be simplified to:

```
>>> Book.objects.aggregate(Avg('price'))
{'price__avg': 34.35}
```

The argument to the `aggregate()` clause describes the aggregate value that we want to compute - in this case, the average of the `price` field on the `Book` model. A list of the aggregate functions that are available can be found in the [QuerySet reference](#).

`aggregate()` is a terminal clause for a `QuerySet` that, when invoked, returns a dictionary of name-value pairs. The name is an identifier for the aggregate value; the value is the computed aggregate. The name is automatically generated from the name of the field and the aggregate function. If you want to manually specify a name for the aggregate value, you can do so by providing that name when you specify the aggregate clause:

```
>>> Book.objects.aggregate(average_price=Avg('price'))
{'average_price': 34.35}
```

If you want to generate more than one aggregate, you just add another argument to the `aggregate()` clause. So, if we also wanted to know the maximum and minimum price of all books, we would issue the query:

```
>>> from django.db.models import Avg, Max, Min
>>> Book.objects.aggregate(Avg('price'), Max('price'), Min('price'))
{'price__avg': 34.35, 'price__max': Decimal('81.20'), 'price__min': Decimal('12.99')}
```

## Generating aggregates for each item in a `QuerySet`

The second way to generate summary values is to generate an independent summary for each object in a `QuerySet`. For example, if you are retrieving a list of books, you may want to know how many authors contributed to each book. Each `Book` has a many-to-many relationship with the `Author`; we want to summarize this relationship for each book in the `QuerySet`.

Per-object summaries can be generated using the `annotate()` clause. When an `annotate()` clause is specified, each object in the `QuerySet` will be annotated with the specified values.

The syntax for these annotations is identical to that used for the `aggregate()` clause. Each argument to `annotate()` describes an aggregate that is to be calculated. For example, to annotate books with the number of authors:

```
# Build an annotated queryset
>>> from django.db.models import Count
>>> q = Book.objects.annotate(Count('authors'))
```

```
# Interrogate the first object in the queryset
>>> q[0]
<Book: The Definitive Guide to Django>
>>> q[0].authors__count
2
# Interrogate the second object in the queryset
>>> q[1]
<Book: Practical Django Projects>
>>> q[1].authors__count
1
```

As with `aggregate()`, the name for the annotation is automatically derived from the name of the aggregate function and the name of the field being aggregated. You can override this default name by providing an alias when you specify the annotation:

```
>>> q = Book.objects.annotate(num_authors=Count('authors'))
>>> q[0].num_authors
2
>>> q[1].num_authors
1
```

Unlike `aggregate()`, `annotate()` is *not* a terminal clause. The output of the `annotate()` clause is a `QuerySet`; this `QuerySet` can be modified using any other `QuerySet` operation, including `filter()`, `order_by()`, or even additional calls to `annotate()`.

## Combining multiple aggregations

Combining multiple aggregations with `annotate()` will **yield the wrong results** because joins are used instead of subqueries:

```
>>> book = Book.objects.first()
>>> book.authors.count()
2
>>> book.store_set.count()
3
>>> q = Book.objects.annotate(Count('authors'), Count('store'))
>>> q[0].authors__count
6
>>> q[0].store__count
6
```

For most aggregates, there is no way to avoid this problem, however, the `Count` aggregate has a `distinct` parameter that may help:

```
>>> q = Book.objects.annotate(Count('authors', distinct=True), Count('store',
↳distinct=True))
>>> q[0].authors__count
2
>>> q[0].store__count
3
```

### If in doubt, inspect the SQL query!

In order to understand what happens in your query, consider inspecting the `query` property of your `QuerySet`.

## Joins and aggregates

So far, we have dealt with aggregates over fields that belong to the model being queried. However, sometimes the value you want to aggregate will belong to a model that is related to the model you are querying.

When specifying the field to be aggregated in an aggregate function, Django will allow you to use the same *double underscore notation* that is used when referring to related fields in filters. Django will then handle any table joins that are required to retrieve and aggregate the related value.

For example, to find the price range of books offered in each store, you could use the annotation:

```
>>> from django.db.models import Max, Min
>>> Store.objects.annotate(min_price=Min('books__price'), max_price=Max('books__price
↳'))
```

This tells Django to retrieve the `Store` model, join (through the many-to-many relationship) with the `Book` model, and aggregate on the price field of the book model to produce a minimum and maximum value.

The same rules apply to the `aggregate()` clause. If you wanted to know the lowest and highest price of any book that is available for sale in any of the stores, you could use the aggregate:

```
>>> Store.objects.aggregate(min_price=Min('books__price'), max_price=Max('books__price
↳'))
```

Join chains can be as deep as you require. For example, to extract the age of the youngest author of any book available for sale, you could issue the query:

```
>>> Store.objects.aggregate(youngest_age=Min('books__authors__age'))
```

## Following relationships backwards

In a way similar to *Lookups that span relationships*, aggregations and annotations on fields of models or models that are related to the one you are querying can include traversing “reverse” relationships. The lowercase name of related models and double-underscores are used here too.

For example, we can ask for all publishers, annotated with their respective total book stock counters (note how we use 'book' to specify the `Publisher -> Book` reverse foreign key hop):

```
>>> from django.db.models import Count, Min, Sum, Avg
>>> Publisher.objects.annotate(Count('book'))
```

(Every `Publisher` in the resulting `QuerySet` will have an extra attribute called `book__count`.)

We can also ask for the oldest book of any of those managed by every publisher:

```
>>> Publisher.objects.aggregate(oldest_pubdate=Min('book__pubdate'))
```

(The resulting dictionary will have a key called 'oldest\_pubdate'. If no such alias were specified, it would be the rather long 'book\_\_pubdate\_\_min'.)

This doesn't apply just to foreign keys. It also works with many-to-many relations. For example, we can ask for every author, annotated with the total number of pages considering all the books the author has (co-)authored (note how we use 'book' to specify the `Author -> Book` reverse many-to-many hop):

```
>>> Author.objects.annotate(total_pages=Sum('book__pages'))
```

(Every `Author` in the resulting `QuerySet` will have an extra attribute called `total_pages`. If no such alias were specified, it would be the rather long `book__pages__sum`.)

Or ask for the average rating of all the books written by author(s) we have on file:

```
>>> Author.objects.aggregate(average_rating=Avg('book__rating'))
```

(The resulting dictionary will have a key called `'average_rating'`. If no such alias were specified, it would be the rather long `'book__rating__avg'`.)

## Aggregations and other `QuerySet` clauses

### `filter()` and `exclude()`

Aggregates can also participate in filters. Any `filter()` (or `exclude()`) applied to normal model fields will have the effect of constraining the objects that are considered for aggregation.

When used with an `annotate()` clause, a filter has the effect of constraining the objects for which an annotation is calculated. For example, you can generate an annotated list of all books that have a title starting with “Django” using the query:

```
>>> from django.db.models import Count, Avg
>>> Book.objects.filter(name__startswith="Django").annotate(num_authors=Count('authors
↪'))
```

When used with an `aggregate()` clause, a filter has the effect of constraining the objects over which the aggregate is calculated. For example, you can generate the average price of all books with a title that starts with “Django” using the query:

```
>>> Book.objects.filter(name__startswith="Django").aggregate(Avg('price'))
```

### Filtering on annotations

Annotated values can also be filtered. The alias for the annotation can be used in `filter()` and `exclude()` clauses in the same way as any other model field.

For example, to generate a list of books that have more than one author, you can issue the query:

```
>>> Book.objects.annotate(num_authors=Count('authors')).filter(num_authors__gt=1)
```

This query generates an annotated result set, and then generates a filter based upon that annotation.

### Order of `annotate()` and `filter()` clauses

When developing a complex query that involves both `annotate()` and `filter()` clauses, pay particular attention to the order in which the clauses are applied to the `QuerySet`.

When an `annotate()` clause is applied to a query, the annotation is computed over the state of the query up to the point where the annotation is requested. The practical implication of this is that `filter()` and `annotate()` are not commutative operations.

Given:

- Publisher A has two books with ratings 4 and 5.

- Publisher B has two books with ratings 1 and 4.
- Publisher C has one book with rating 1.

Here's an example with the `Count` aggregate:

```
>>> a, b = Publisher.objects.annotate(num_books=Count('book', distinct=True)).
↳filter(book__rating__gt=3.0)
>>> a, a.num_books
(<Publisher: A>, 2)
>>> b, b.num_books
(<Publisher: B>, 2)

>>> a, b = Publisher.objects.filter(book__rating__gt=3.0).annotate(num_books=Count(
↳'book'))
>>> a, a.num_books
(<Publisher: A>, 2)
>>> b, b.num_books
(<Publisher: B>, 1)
```

Both queries return a list of publishers that have at least one book with a rating exceeding 3.0, hence publisher C is excluded.

In the first query, the annotation precedes the filter, so the filter has no effect on the annotation. `distinct=True` is required to avoid a *query bug*.

The second query counts the number of books that have a rating exceeding 3.0 for each publisher. The filter precedes the annotation, so the filter constrains the objects considered when calculating the annotation.

Here's another example with the `Avg` aggregate:

```
>>> a, b = Publisher.objects.annotate(avg_rating=Avg('book__rating')).filter(book__
↳rating__gt=3.0)
>>> a, a.avg_rating
(<Publisher: A>, 4.5) # (5+4)/2
>>> b, b.avg_rating
(<Publisher: B>, 2.5) # (1+4)/2

>>> a, b = Publisher.objects.filter(book__rating__gt=3.0).annotate(avg_rating=Avg(
↳'book__rating'))
>>> a, a.avg_rating
(<Publisher: A>, 4.5) # (5+4)/2
>>> b, b.avg_rating
(<Publisher: B>, 4.0) # 4/1 (book with rating 1 excluded)
```

The first query asks for the average rating of all a publisher's books for publisher's that have at least one book with a rating exceeding 3.0. The second query asks for the average of a publisher's book's ratings for only those ratings exceeding 3.0.

It's difficult to intuit how the ORM will translate complex querysets into SQL queries so when in doubt, inspect the SQL with `str(queryset.query)` and write plenty of tests.

### `order_by()`

Annotations can be used as a basis for ordering. When you define an `order_by()` clause, the aggregates you provide can reference any alias defined as part of an `annotate()` clause in the query.

For example, to order a `QuerySet` of books by the number of authors that have contributed to the book, you could use the following query:

```
>>> Book.objects.annotate(num_authors=Count('authors')).order_by('num_authors')
```

### values()

Ordinarily, annotations are generated on a per-object basis - an annotated `QuerySet` will return one result for each object in the original `QuerySet`. However, when a `values()` clause is used to constrain the columns that are returned in the result set, the method for evaluating annotations is slightly different. Instead of returning an annotated result for each result in the original `QuerySet`, the original results are grouped according to the unique combinations of the fields specified in the `values()` clause. An annotation is then provided for each unique group; the annotation is computed over all members of the group.

For example, consider an author query that attempts to find out the average rating of books written by each author:

```
>>> Author.objects.annotate(average_rating=Avg('book__rating'))
```

This will return one result for each author in the database, annotated with their average book rating.

However, the result will be slightly different if you use a `values()` clause:

```
>>> Author.objects.values('name').annotate(average_rating=Avg('book__rating'))
```

In this example, the authors will be grouped by name, so you will only get an annotated result for each *unique* author name. This means if you have two authors with the same name, their results will be merged into a single result in the output of the query; the average will be computed as the average over the books written by both authors.

### Order of annotate() and values() clauses

As with the `filter()` clause, the order in which `annotate()` and `values()` clauses are applied to a query is significant. If the `values()` clause precedes the `annotate()`, the annotation will be computed using the grouping described by the `values()` clause.

However, if the `annotate()` clause precedes the `values()` clause, the annotations will be generated over the entire query set. In this case, the `values()` clause only constrains the fields that are generated on output.

For example, if we reverse the order of the `values()` and `annotate()` clause from our previous example:

```
>>> Author.objects.annotate(average_rating=Avg('book__rating')).values('name',
↳ 'average_rating')
```

This will now yield one unique result for each author; however, only the author's name and the `average_rating` annotation will be returned in the output data.

You should also note that `average_rating` has been explicitly included in the list of values to be returned. This is required because of the ordering of the `values()` and `annotate()` clause.

If the `values()` clause precedes the `annotate()` clause, any annotations will be automatically added to the result set. However, if the `values()` clause is applied after the `annotate()` clause, you need to explicitly include the aggregate column.

### Interaction with default ordering or order\_by()

Fields that are mentioned in the `order_by()` part of a queryset (or which are used in the default ordering on a model) are used when selecting the output data, even if they are not otherwise specified in the `values()` call. These

extra fields are used to group “like” results together and they can make otherwise identical result rows appear to be separate. This shows up, particularly, when counting things.

By way of example, suppose you have a model like this:

```
from django.db import models

class Item(models.Model):
    name = models.CharField(max_length=10)
    data = models.IntegerField()

    class Meta:
        ordering = ["name"]
```

The important part here is the default ordering on the name field. If you want to count how many times each distinct data value appears, you might try this:

```
# Warning: not quite correct!
Item.objects.values("data").annotate(Count("id"))
```

...which will group the Item objects by their common data values and then count the number of id values in each group. Except that it won't quite work. The default ordering by name will also play a part in the grouping, so this query will group by distinct (data, name) pairs, which isn't what you want. Instead, you should construct this queryset:

```
Item.objects.values("data").annotate(Count("id")).order_by()
```

...clearing any ordering in the query. You could also order by, say, data without any harmful effects, since that is already playing a role in the query.

This behavior is the same as that noted in the queryset documentation for *distinct()* and the general rule is the same: normally you won't want extra columns playing a part in the result, so clear out the ordering, or at least make sure it's restricted only to those fields you also select in a *values()* call.

---

**Note:** You might reasonably ask why Django doesn't remove the extraneous columns for you. The main reason is consistency with *distinct()* and other places: Django **never** removes ordering constraints that you have specified (and we can't change those other methods' behavior, as that would violate our *API stability* policy).

---

## Aggregating annotations

You can also generate an aggregate on the result of an annotation. When you define an *aggregate()* clause, the aggregates you provide can reference any alias defined as part of an *annotate()* clause in the query.

For example, if you wanted to calculate the average number of authors per book you first annotate the set of books with the author count, then aggregate that author count, referencing the annotation field:

```
>>> from django.db.models import Count, Avg
>>> Book.objects.annotate(num_authors=Count('authors')).aggregate(Avg('num_authors'))
{'num_authors__avg': 1.66}
```

## 3.2.4 Search

A common task for web applications is to search some data in the database with user input. In a simple case, this could be filtering a list of objects by a category. A more complex use case might require searching with weighting,

categorization, highlighting, multiple languages, and so on. This document explains some of the possible use cases and the tools you can use.

We'll refer to the same models used in *Making queries*.

## Use Cases

### Standard textual queries

Text-based fields have a selection of simple matching operations. For example, you may wish to allow lookup up an author like so:

```
>>> Author.objects.filter(name__contains='Terry')
[<Author: Terry Gilliam>, <Author: Terry Jones>]
```

This is a very fragile solution as it requires the user to know an exact substring of the author's name. A better approach could be a case-insensitive match (*icontains*), but this is only marginally better.

### A database's more advanced comparison functions

If you're using PostgreSQL, Django provides *a selection of database specific tools* to allow you to leverage more complex querying options. Other databases have different selections of tools, possibly via plugins or user-defined functions. Django doesn't include any support for them at this time. We'll use some examples from PostgreSQL to demonstrate the kind of functionality databases may have.

---

#### Searching in other databases

All of the searching tools provided by *django.contrib.postgres* are constructed entirely on public APIs such as *custom lookups* and *database functions*. Depending on your database, you should be able to construct queries to allow similar APIs. If there are specific things which cannot be achieved this way, please open a ticket.

In the above example, we determined that a case insensitive lookup would be more useful. When dealing with non-English names, a further improvement is to use *unaccented comparison*:

```
>>> Author.objects.filter(name__unaccent__icontains='Helen')
[<Author: Helen Mirren>, <Author: Helena Bonham Carter>, <Author: H  l  ne Joy>]
```

This shows another issue, where we are matching against a different spelling of the name. In this case we have an asymmetry though - a search for Helen will pick up Helena or H  l  ne, but not the reverse. Another option would be to use a *trigram\_similar* comparison, which compares sequences of letters.

For example:

```
>>> Author.objects.filter(name__unaccent__lower__trigram_similar='H  l  ne')
[<Author: Helen Mirren>, <Author: H  l  ne Joy>]
```

Now we have a different problem - the longer name of "Helena Bonham Carter" doesn't show up as it is much longer. Trigram searches consider all combinations of three letters, and compares how many appear in both search and source strings. For the longer name, there are more combinations which appear in the source string so it is no longer considered a close match.

The correct choice of comparison functions here depends on your particular data set, for example the language(s) used and the type of text being searched. All of the examples we've seen are on short strings where the user is likely to enter something close (by varying definitions) to the source data.

## Document-based search

Simple database operations are too simple an approach when you start considering large blocks of text. Whereas the examples above can be thought of as operations on a string of characters, full text search looks at the actual words. Depending on the system used, it's likely to use some of the following ideas:

- Ignoring “stop words” such as “a”, “the”, “and”.
- Stemming words, so that “pony” and “ponies” are considered similar.
- Weighting words based on different criteria such as how frequently they appear in the text, or the importance of the fields, such as the title or keywords, that they appear in.

There are many alternatives for using searching software, some of the most prominent are [Elastic](#) and [Solr](#). These are full document-based search solutions. To use them with data from Django models, you'll need a layer which translates your data into a textual document, including back-references to the database ids. When a search using the engine returns a certain document, you can then look it up in the database. There are a variety of third-party libraries which are designed to help with this process.

## PostgreSQL support

PostgreSQL has its own full text search implementation built-in. While not as powerful as some other search engines, it has the advantage of being inside your database and so can easily be combined with other relational queries such as categorization.

The `django.contrib.postgres` module provides some helpers to make these queries. For example, a simple query might be to select all the blog entries which mention “cheese”:

```
>>> Entry.objects.filter(body_text__search='cheese')
[<Entry: Cheese on Toast recipes>, <Entry: Pizza recipes>]
```

You can also filter on a combination of fields and on related models:

```
>>> Entry.objects.annotate(
...     search=SearchVector('blog__tagline', 'body_text'),
... ).filter(search='cheese')
[
  <Entry: Cheese on Toast recipes>,
  <Entry: Pizza Recipes>,
  <Entry: Dairy farming in Argentina>,
]
```

See the `contrib.postgres` [Full text search](#) document for complete details.

## 3.2.5 Managers

### class `Manager`

A `Manager` is the interface through which database query operations are provided to Django models. At least one `Manager` exists for every model in a Django application.

The way `Manager` classes work is documented in [Making queries](#); this document specifically touches on model options that customize `Manager` behavior.

## Manager names

By default, Django adds a `Manager` with the name `objects` to every Django model class. However, if you want to use `objects` as a field name, or if you want to use a name other than `objects` for the `Manager`, you can rename it on a per-model basis. To rename the `Manager` for a given class, define a class attribute of type `models.Manager()` on that model. For example:

```
from django.db import models

class Person(models.Model):
    #...
    people = models.Manager()
```

Using this example model, `Person.objects` will generate an `AttributeError` exception, but `Person.people.all()` will provide a list of all `Person` objects.

## Custom managers

You can use a custom `Manager` in a particular model by extending the base `Manager` class and instantiating your custom `Manager` in your model.

There are two reasons you might want to customize a `Manager`: to add extra `Manager` methods, and/or to modify the initial `QuerySet` the `Manager` returns.

## Adding extra manager methods

Adding extra `Manager` methods is the preferred way to add “table-level” functionality to your models. (For “row-level” functionality – i.e., functions that act on a single instance of a model object – use *Model methods*, not custom `Manager` methods.)

A custom `Manager` method can return anything you want. It doesn’t have to return a `QuerySet`.

For example, this custom `Manager` offers a method `with_counts()`, which returns a list of all `OpinionPoll` objects, each with an extra `num_responses` attribute that is the result of an aggregate query:

```
from django.db import models

class PollManager(models.Manager):
    def with_counts(self):
        from django.db import connection
        with connection.cursor() as cursor:
            cursor.execute("""
                SELECT p.id, p.question, p.poll_date, COUNT(*)
                FROM polls_opinionpoll p, polls_response r
                WHERE p.id = r.poll_id
                GROUP BY p.id, p.question, p.poll_date
                ORDER BY p.poll_date DESC""")
            result_list = []
            for row in cursor.fetchall():
                p = self.model(id=row[0], question=row[1], poll_date=row[2])
                p.num_responses = row[3]
                result_list.append(p)
            return result_list

class OpinionPoll(models.Model):
    question = models.CharField(max_length=200)
```

```
poll_date = models.DateField()
objects = PollManager()

class Response(models.Model):
    poll = models.ForeignKey(OpinionPoll, on_delete=models.CASCADE)
    person_name = models.CharField(max_length=50)
    response = models.TextField()
```

With this example, you'd use `OpinionPoll.objects.with_counts()` to return that list of `OpinionPoll` objects with `num_responses` attributes.

Another thing to note about this example is that `Manager` methods can access `self.model` to get the model class to which they're attached.

### Modifying a manager's initial `QuerySet`

A `Manager`'s base `QuerySet` returns all objects in the system. For example, using this model:

```
from django.db import models

class Book(models.Model):
    title = models.CharField(max_length=100)
    author = models.CharField(max_length=50)
```

...the statement `Book.objects.all()` will return all books in the database.

You can override a `Manager`'s base `QuerySet` by overriding the `Manager.get_queryset()` method. `get_queryset()` should return a `QuerySet` with the properties you require.

For example, the following model has *two* `Managers` – one that returns all objects, and one that returns only the books by Roald Dahl:

```
# First, define the Manager subclass.
class DahlBookManager(models.Manager):
    def get_queryset(self):
        return super(DahlBookManager, self).get_queryset().filter(author='Roald Dahl')

# Then hook it into the Book model explicitly.
class Book(models.Model):
    title = models.CharField(max_length=100)
    author = models.CharField(max_length=50)

    objects = models.Manager() # The default manager.
    dahl_objects = DahlBookManager() # The Dahl-specific manager.
```

With this sample model, `Book.objects.all()` will return all books in the database, but `Book.dahl_objects.all()` will only return the ones written by Roald Dahl.

Of course, because `get_queryset()` returns a `QuerySet` object, you can use `filter()`, `exclude()` and all the other `QuerySet` methods on it. So these statements are all legal:

```
Book.dahl_objects.all()
Book.dahl_objects.filter(title='Matilda')
Book.dahl_objects.count()
```

This example also pointed out another interesting technique: using multiple managers on the same model. You can attach as many `Manager()` instances to a model as you'd like. This is an easy way to define common “filters” for

your models.

For example:

```
class AuthorManager(models.Manager):
    def get_queryset(self):
        return super(AuthorManager, self).get_queryset().filter(role='A')

class EditorManager(models.Manager):
    def get_queryset(self):
        return super(EditorManager, self).get_queryset().filter(role='E')

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)
    role = models.CharField(max_length=1, choices=(('A', _('Author')), ('E', _('Editor
↵'))))
    people = models.Manager()
    authors = AuthorManager()
    editors = EditorManager()
```

This example allows you to request `Person.authors.all()`, `Person.editors.all()`, and `Person.people.all()`, yielding predictable results.

## Default managers

### `Model._default_manager`

If you use custom `Manager` objects, take note that the first `Manager` Django encounters (in the order in which they're defined in the model) has a special status. Django interprets the first `Manager` defined in a class as the “default” `Manager`, and several parts of Django (including `dumpdata`) will use that `Manager` exclusively for that model. As a result, it's a good idea to be careful in your choice of default manager in order to avoid a situation where overriding `get_queryset()` results in an inability to retrieve objects you'd like to work with.

You can specify a custom default manager using `Meta.default_manager_name`.

If you're writing some code that must handle an unknown model, for example, in a third-party app that implements a generic view, use this manager (or `_base_manager`) rather than assuming the model has an `objects` manager.

## Base managers

### `Model._base_manager`

## Using managers for related object access

By default, Django uses an instance of the `Model._base_manager` manager class when accessing related objects (i.e. `choice.question`), not the `_default_manager` on the related object. This is because Django needs to be able to retrieve the related object, even if it would otherwise be filtered out (and hence be inaccessible) by the default manager.

If the normal base manager class (`django.db.models.Manager`) isn't appropriate for your circumstances, you can tell Django which class to use by setting `Meta.base_manager_name`.

`Manager`'s aren't used when querying on related models. For example, if the `Question` model *from the tutorial* had a `deleted` field and a base manager that filters out instances with `deleted=True`, a queryset like

`Choice.objects.filter(question__name__startswith='What')` would include choices related to deleted questions.

### Don't filter away any results in this type of manager subclass

This manager is used to access objects that are related to from some other model. In those situations, Django has to be able to see all the objects for the model it is fetching, so that *anything* which is referred to can be retrieved.

If you override the `get_queryset()` method and filter out any rows, Django will return incorrect results. Don't do that. A manager that filters results in `get_queryset()` is not appropriate for use as a base manager.

### Calling custom `QuerySet` methods from the manager

While most methods from the standard `QuerySet` are accessible directly from the `Manager`, this is only the case for the extra methods defined on a custom `QuerySet` if you also implement them on the `Manager`:

```
class PersonQuerySet(models.QuerySet):
    def authors(self):
        return self.filter(role='A')

    def editors(self):
        return self.filter(role='E')

class PersonManager(models.Manager):
    def get_queryset(self):
        return PersonQuerySet(self.model, using=self._db)

    def authors(self):
        return self.get_queryset().authors()

    def editors(self):
        return self.get_queryset().editors()

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)
    role = models.CharField(max_length=1, choices=(('A', _('Author')), ('E', _('Editor
↪'))))
    people = PersonManager()
```

This example allows you to call both `authors()` and `editors()` directly from the manager `Person.people`.

### Creating a manager with `QuerySet` methods

In lieu of the above approach which requires duplicating methods on both the `QuerySet` and the `Manager`, `QuerySet.as_manager()` can be used to create an instance of `Manager` with a copy of a custom `QuerySet`'s methods:

```
class Person(models.Model):
    ...
    people = PersonQuerySet.as_manager()
```

The `Manager` instance created by `QuerySet.as_manager()` will be virtually identical to the `PersonManager` from the previous example.

Not every `QuerySet` method makes sense at the `Manager` level; for instance we intentionally prevent the `QuerySet.delete()` method from being copied onto the `Manager` class.

Methods are copied according to the following rules:

- Public methods are copied by default.
- Private methods (starting with an underscore) are not copied by default.
- Methods with a `queryset_only` attribute set to `False` are always copied.
- Methods with a `queryset_only` attribute set to `True` are never copied.

For example:

```
class CustomQuerySet(models.QuerySet):
    # Available on both Manager and QuerySet.
    def public_method(self):
        return

    # Available only on QuerySet.
    def _private_method(self):
        return

    # Available only on QuerySet.
    def opted_out_public_method(self):
        return
    opted_out_public_method.queryset_only = True

    # Available on both Manager and QuerySet.
    def _opted_in_private_method(self):
        return
    _opted_in_private_method.queryset_only = False
```

`from_queryset()`

`classmethod from_queryset(queryset_class)`

For advanced usage you might want both a custom `Manager` and a custom `QuerySet`. You can do that by calling `Manager.from_queryset()` which returns a *subclass* of your base `Manager` with a copy of the custom `QuerySet` methods:

```
class BaseManager(models.Manager):
    def manager_only_method(self):
        return

class CustomQuerySet(models.QuerySet):
    def manager_and_queryset_method(self):
        return

class MyModel(models.Model):
    objects = BaseManager.from_queryset(CustomQuerySet)()
```

You may also store the generated class into a variable:

```
CustomManager = BaseManager.from_queryset(CustomQuerySet)

class MyModel(models.Model):
    objects = CustomManager()
```

## Custom managers and model inheritance

Here's how Django handles custom managers and *model inheritance*:

1. Managers from base classes are always inherited by the child class, using Python's normal name resolution order (names on the child class override all others; then come names on the first parent class, and so on).
2. If no managers are declared on a model and/or its parents, Django automatically creates the `objects` manager.
3. The default manager on a class is either the one chosen with `Meta.default_manager_name`, or the first manager declared on the model, or the default manager of the first parent model.

Some inheritance behaviors described above don't apply unless you set `manager_inheritance_from_future = True` on the model's `Meta` class. In older versions and if you don't set that attribute, manager inheritance varies depending on the type of model inheritance (*Abstract base classes*, *Multi-table inheritance*, or *Proxy models*), especially with regards to electing the default manager.

These rules provide the necessary flexibility if you want to install a collection of custom managers on a group of models, via an abstract base class, but still customize the default manager. For example, suppose you have this base class:

```
class AbstractBase(models.Model):
    # ...
    objects = CustomManager()

    class Meta:
        abstract = True
```

If you use this directly in a subclass, `objects` will be the default manager if you declare no managers in the base class:

```
class ChildA(AbstractBase):
    # ...
    # This class has CustomManager as the default manager.
    pass
```

If you want to inherit from `AbstractBase`, but provide a different default manager, you can provide the default manager on the child class:

```
class ChildB(AbstractBase):
    # ...
    # An explicit default manager.
    default_manager = OtherManager()
```

Here, `default_manager` is the default. The `objects` manager is still available, since it's inherited. It just isn't used as the default.

Finally for this example, suppose you want to add extra managers to the child class, but still use the default from `AbstractBase`. You can't add the new manager directly in the child class, as that would override the default and you would have to also explicitly include all the managers from the abstract base class. The solution is to put the extra managers in another base class and introduce it into the inheritance hierarchy *after* the defaults:

```
class ExtraManager(models.Model):
    extra_manager = OtherManager()

    class Meta:
        abstract = True

class ChildC(AbstractBase, ExtraManager):
```

```
# ...
# Default manager is CustomManager, but OtherManager is
# also available via the "extra_manager" attribute.
pass
```

Note that while you can *define* a custom manager on the abstract model, you can't *invoke* any methods using the abstract model. That is:

```
ClassA.objects.do_something()
```

is legal, but:

```
AbstractBase.objects.do_something()
```

will raise an exception. This is because managers are intended to encapsulate logic for managing collections of objects. Since you can't have a collection of abstract objects, it doesn't make sense to be managing them. If you have functionality that applies to the abstract model, you should put that functionality in a `staticmethod` or `classmethod` on the abstract model.

## Implementation concerns

Whatever features you add to your custom `Manager`, it must be possible to make a shallow copy of a `Manager` instance; i.e., the following code must work:

```
>>> import copy
>>> manager = MyManager()
>>> my_copy = copy.copy(manager)
```

Django makes shallow copies of manager objects during certain queries; if your `Manager` cannot be copied, those queries will fail.

This won't be an issue for most custom managers. If you are just adding simple methods to your `Manager`, it is unlikely that you will inadvertently make instances of your `Manager` uncopyable. However, if you're overriding `__getattr__` or some other private method of your `Manager` object that controls object state, you should ensure that you don't affect the ability of your `Manager` to be copied.

### 3.2.6 Performing raw SQL queries

When the *model query APIs* don't go far enough, you can fall back to writing raw SQL. Django gives you two ways of performing raw SQL queries: you can use `Manager.raw()` to *perform raw queries and return model instances*, or you can avoid the model layer entirely and *execute custom SQL directly*.

**Warning:** You should be very careful whenever you write raw SQL. Every time you use it, you should properly escape any parameters that the user can control by using `params` in order to protect against SQL injection attacks. Please read more about *SQL injection protection*.

#### Performing raw queries

The `raw()` manager method can be used to perform raw SQL queries that return model instances:

```
Manager.raw(raw_query, params=None, translations=None)
```

This method takes a raw SQL query, executes it, and returns a `django.db.models.query.RawQuerySet` instance. This `RawQuerySet` instance can be iterated over just like a normal `QuerySet` to provide object instances.

This is best illustrated with an example. Suppose you have the following model:

```
class Person(models.Model):
    first_name = models.CharField(...)
    last_name = models.CharField(...)
    birth_date = models.DateField(...)
```

You could then execute custom SQL like so:

```
>>> for p in Person.objects.raw('SELECT * FROM myapp_person'):
...     print(p)
John Smith
Jane Jones
```

Of course, this example isn't very exciting – it's exactly the same as running `Person.objects.all()`. However, `raw()` has a bunch of other options that make it very powerful.

---

### Model table names

Where did the name of the `Person` table come from in that example?

By default, Django figures out a database table name by joining the model's "app label" – the name you used in `manage.py startapp` – to the model's class name, with an underscore between them. In the example we've assumed that the `Person` model lives in an app named `myapp`, so its table would be `myapp_person`.

For more details check out the documentation for the `db_table` option, which also lets you manually set the database table name.

**Warning:** No checking is done on the SQL statement that is passed in to `.raw()`. Django expects that the statement will return a set of rows from the database, but does nothing to enforce that. If the query does not return rows, a (possibly cryptic) error will result.

**Warning:** If you are performing queries on MySQL, note that MySQL's silent type coercion may cause unexpected results when mixing types. If you query on a string type column, but with an integer value, MySQL will coerce the types of all values in the table to an integer before performing the comparison. For example, if your table contains the values `'abc'`, `'def'` and you query for `WHERE mycolumn=0`, both rows will match. To prevent this, perform the correct typecasting before using the value in a query.

**Warning:** While a `RawQuerySet` instance can be iterated over like a normal `QuerySet`, `RawQuerySet` doesn't implement all methods you can use with `QuerySet`. For example, `__bool__()` and `__len__()` are not defined in `RawQuerySet`, and thus all `RawQuerySet` instances are considered `True`. The reason these methods are not implemented in `RawQuerySet` is that implementing them without internal caching would be a performance drawback and adding such caching would be backward incompatible.

## Mapping query fields to model fields

`raw()` automatically maps fields in the query to fields on the model.

The order of fields in your query doesn't matter. In other words, both of the following queries work identically:

```
>>> Person.objects.raw('SELECT id, first_name, last_name, birth_date FROM myapp_person
↳')
...
>>> Person.objects.raw('SELECT last_name, birth_date, first_name, id FROM myapp_person
↳')
...
```

Matching is done by name. This means that you can use SQL's AS clauses to map fields in the query to model fields. So if you had some other table that had `Person` data in it, you could easily map it into `Person` instances:

```
>>> Person.objects.raw('''SELECT first AS first_name,
...                          last AS last_name,
...                          bd AS birth_date,
...                          pk AS id,
...                          FROM some_other_table''')
```

As long as the names match, the model instances will be created correctly.

Alternatively, you can map fields in the query to model fields using the `translations` argument to `raw()`. This is a dictionary mapping names of fields in the query to names of fields on the model. For example, the above query could also be written:

```
>>> name_map = {'first': 'first_name', 'last': 'last_name', 'bd': 'birth_date', 'pk':
↳'id'}
>>> Person.objects.raw('SELECT * FROM some_other_table', translations=name_map)
```

## Index lookups

`raw()` supports indexing, so if you need only the first result you can write:

```
>>> first_person = Person.objects.raw('SELECT * FROM myapp_person')[0]
```

However, the indexing and slicing are not performed at the database level. If you have a large number of `Person` objects in your database, it is more efficient to limit the query at the SQL level:

```
>>> first_person = Person.objects.raw('SELECT * FROM myapp_person LIMIT 1')[0]
```

## Deferring model fields

Fields may also be left out:

```
>>> people = Person.objects.raw('SELECT id, first_name FROM myapp_person')
```

The `Person` objects returned by this query will be deferred model instances (see `defer()`). This means that the fields that are omitted from the query will be loaded on demand. For example:

```
>>> for p in Person.objects.raw('SELECT id, first_name FROM myapp_person'):
...     print(p.first_name, # This will be retrieved by the original query)
```

```
...         p.last_name) # This will be retrieved on demand
...
John Smith
Jane Jones
```

From outward appearances, this looks like the query has retrieved both the first name and last name. However, this example actually issued 3 queries. Only the first names were retrieved by the `raw()` query – the last names were both retrieved on demand when they were printed.

There is only one field that you can't leave out - the primary key field. Django uses the primary key to identify model instances, so it must always be included in a raw query. An `InvalidQuery` exception will be raised if you forget to include the primary key.

## Adding annotations

You can also execute queries containing fields that aren't defined on the model. For example, we could use PostgreSQL's `age()` function to get a list of people with their ages calculated by the database:

```
>>> people = Person.objects.raw('SELECT *, age(birth_date) AS age FROM myapp_person')
>>> for p in people:
...     print("%s is %s." % (p.first_name, p.age))
John is 37.
Jane is 42.
...
```

## Passing parameters into `raw()`

If you need to perform parameterized queries, you can use the `params` argument to `raw()`:

```
>>> lname = 'Doe'
>>> Person.objects.raw('SELECT * FROM myapp_person WHERE last_name = %s', [lname])
```

`params` is a list or dictionary of parameters. You'll use `%s` placeholders in the query string for a list, or `%(key)s` placeholders for a dictionary (where `key` is replaced by a dictionary key, of course), regardless of your database engine. Such placeholders will be replaced with parameters from the `params` argument.

---

**Note:** Dictionary params are not supported with the SQLite backend; with this backend, you must pass parameters as a list.

---

### **Warning: Do not use string formatting on raw queries!**

It's tempting to write the above query as:

```
>>> query = 'SELECT * FROM myapp_person WHERE last_name = %s' % lname
>>> Person.objects.raw(query)
```

### **Don't.**

Using the `params` argument completely protects you from [SQL injection attacks](#), a common exploit where attackers inject arbitrary SQL into your database. If you use string interpolation, sooner or later you'll fall victim to SQL injection. As long as you remember to always use the `params` argument you'll be protected.

## Executing custom SQL directly

Sometimes even `Manager.raw()` isn't quite enough: you might need to perform queries that don't map cleanly to models, or directly execute UPDATE, INSERT, or DELETE queries.

In these cases, you can always access the database directly, routing around the model layer entirely.

The object `django.db.connection` represents the default database connection. To use the database connection, call `connection.cursor()` to get a cursor object. Then, call `cursor.execute(sql, [params])` to execute the SQL and `cursor.fetchone()` or `cursor.fetchall()` to return the resulting rows.

For example:

```
from django.db import connection

def my_custom_sql(self):
    with connection.cursor() as cursor:
        cursor.execute("UPDATE bar SET foo = 1 WHERE baz = %s", [self.baz])
        cursor.execute("SELECT foo FROM bar WHERE baz = %s", [self.baz])
        row = cursor.fetchone()

    return row
```

Note that if you want to include literal percent signs in the query, you have to double them in the case you are passing parameters:

```
cursor.execute("SELECT foo FROM bar WHERE baz = '30%'")
cursor.execute("SELECT foo FROM bar WHERE baz = '30%%' AND id = %s", [self.id])
```

If you are using *more than one database*, you can use `django.db.connections` to obtain the connection (and cursor) for a specific database. `django.db.connections` is a dictionary-like object that allows you to retrieve a specific connection using its alias:

```
from django.db import connections
cursor = connections['my_db_alias'].cursor()
# Your code here...
```

By default, the Python DB API will return results without their field names, which means you end up with a list of values, rather than a dict. At a small performance and memory cost, you can return results as a dict by using something like this:

```
def dictfetchall(cursor):
    """Return all rows from a cursor as a dict"""
    columns = [col[0] for col in cursor.description]
    return [
        dict(zip(columns, row))
        for row in cursor.fetchall()
    ]
```

Another option is to use `collections.namedtuple()` from the Python standard library. A `namedtuple` is a tuple-like object that has fields accessible by attribute lookup; it's also indexable and iterable. Results are immutable and accessible by field names or indices, which might be useful:

```
from collections import namedtuple

def namedtuplefetchall(cursor):
    """Return all rows from a cursor as a namedtuple"""
    desc = cursor.description
```

```
nt_result = namedtuple('Result', [col[0] for col in desc])
return [nt_result(*row) for row in cursor.fetchall()]
```

Here is an example of the difference between the three:

```
>>> cursor.execute("SELECT id, parent_id FROM test LIMIT 2");
>>> cursor.fetchall()
((54360982, None), (54360880, None))

>>> cursor.execute("SELECT id, parent_id FROM test LIMIT 2");
>>> dictfetchall(cursor)
[{'parent_id': None, 'id': 54360982}, {'parent_id': None, 'id': 54360880}]

>>> cursor.execute("SELECT id, parent_id FROM test LIMIT 2");
>>> results = namedtuplefetchall(cursor)
>>> results
[Result(id=54360982, parent_id=None), Result(id=54360880, parent_id=None)]
>>> results[0].id
54360982
>>> results[0][0]
54360982
```

## Connections and cursors

`connection` and `cursor` mostly implement the standard Python DB-API described in [PEP 249](#) — except when it comes to *transaction handling*.

If you're not familiar with the Python DB-API, note that the SQL statement in `cursor.execute()` uses placeholders, "%s", rather than adding parameters directly within the SQL. If you use this technique, the underlying database library will automatically escape your parameters as necessary.

Also note that Django expects the "%s" placeholder, *not* the "?" placeholder, which is used by the SQLite Python bindings. This is for the sake of consistency and sanity.

Using a cursor as a context manager:

```
with connection.cursor() as c:
    c.execute(...)
```

is equivalent to:

```
c = connection.cursor()
try:
    c.execute(...)
finally:
    c.close()
```

## 3.2.7 Database transactions

Django gives you a few ways to control how database transactions are managed.

## Managing database transactions

### Django's default transaction behavior

Django's default behavior is to run in autocommit mode. Each query is immediately committed to the database, unless a transaction is active. *See below for details.*

Django uses transactions or savepoints automatically to guarantee the integrity of ORM operations that require multiple queries, especially *delete()* and *update()* queries.

Django's *TestCase* class also wraps each test in a transaction for performance reasons.

### Tying transactions to HTTP requests

A common way to handle transactions on the web is to wrap each request in a transaction. Set *ATOMIC\_REQUESTS* to *True* in the configuration of each database for which you want to enable this behavior.

It works like this. Before calling a view function, Django starts a transaction. If the response is produced without problems, Django commits the transaction. If the view produces an exception, Django rolls back the transaction.

You may perform subtransactions using savepoints in your view code, typically with the *atomic()* context manager. However, at the end of the view, either all or none of the changes will be committed.

**Warning:** While the simplicity of this transaction model is appealing, it also makes it inefficient when traffic increases. Opening a transaction for every view has some overhead. The impact on performance depends on the query patterns of your application and on how well your database handles locking.

---

### Per-request transactions and streaming responses

When a view returns a *StreamingHttpResponse*, reading the contents of the response will often execute code to generate the content. Since the view has already returned, such code runs outside of the transaction.

Generally speaking, it isn't advisable to write to the database while generating a streaming response, since there's no sensible way to handle errors after starting to send the response.

In practice, this feature simply wraps every view function in the *atomic()* decorator described below.

Note that only the execution of your view is enclosed in the transactions. Middleware runs outside of the transaction, and so does the rendering of template responses.

When *ATOMIC\_REQUESTS* is enabled, it's still possible to prevent views from running in a transaction.

**non\_atomic\_requests** (*using=None*)

This decorator will negate the effect of *ATOMIC\_REQUESTS* for a given view:

```
from django.db import transaction

@transaction.non_atomic_requests
def my_view(request):
    do_stuff()

@transaction.non_atomic_requests(using='other')
def my_other_view(request):
    do_stuff_on_the_other_database()
```

It only works if it's applied to the view itself.

## Controlling transactions explicitly

Django provides a single API to control database transactions.

**atomic** (*using=None, savepoint=True*)

Atomicity is the defining property of database transactions. `atomic` allows us to create a block of code within which the atomicity on the database is guaranteed. If the block of code is successfully completed, the changes are committed to the database. If there is an exception, the changes are rolled back.

`atomic` blocks can be nested. In this case, when an inner block completes successfully, its effects can still be rolled back if an exception is raised in the outer block at a later point.

`atomic` is usable both as a [decorator](#):

```
from django.db import transaction

@transaction.atomic
def viewfunc(request):
    # This code executes inside a transaction.
    do_stuff()
```

and as a [context manager](#):

```
from django.db import transaction

def viewfunc(request):
    # This code executes in autocommit mode (Django's default).
    do_stuff()

    with transaction.atomic():
        # This code executes inside a transaction.
        do_more_stuff()
```

Wrapping `atomic` in a `try/except` block allows for natural handling of integrity errors:

```
from django.db import IntegrityError, transaction

@transaction.atomic
def viewfunc(request):
    create_parent()

    try:
        with transaction.atomic():
            generate_relationships()
    except IntegrityError:
        handle_exception()

    add_children()
```

In this example, even if `generate_relationships()` causes a database error by breaking an integrity constraint, you can execute queries in `add_children()`, and the changes from `create_parent()` are still there. Note that any operations attempted in `generate_relationships()` will already have been rolled back safely when `handle_exception()` is called, so the exception handler can also operate on the database if necessary.

### Avoid catching exceptions inside `atomic`!

When exiting an `atomic` block, Django looks at whether it's exited normally or with an exception to determine whether to commit or roll back. If you catch and handle exceptions inside an `atomic` block, you may hide from Django the fact that a problem has happened. This can result in unexpected behavior.

This is mostly a concern for `DatabaseError` and its subclasses such as `IntegrityError`. After such an error, the transaction is broken and Django will perform a rollback at the end of the `atomic` block. If you attempt to run database queries before the rollback happens, Django will raise a `TransactionManagementError`. You may also encounter this behavior when an ORM-related signal handler raises an exception.

The correct way to catch database errors is around an `atomic` block as shown above. If necessary, add an extra `atomic` block for this purpose. This pattern has another advantage: it delimits explicitly which operations will be rolled back if an exception occurs.

If you catch exceptions raised by raw SQL queries, Django's behavior is unspecified and database-dependent.

---

In order to guarantee atomicity, `atomic` disables some APIs. Attempting to commit, roll back, or change the autocommit state of the database connection within an `atomic` block will raise an exception.

`atomic` takes a `using` argument which should be the name of a database. If this argument isn't provided, Django uses the "default" database.

Under the hood, Django's transaction management code:

- opens a transaction when entering the outermost `atomic` block;
- creates a savepoint when entering an inner `atomic` block;
- releases or rolls back to the savepoint when exiting an inner block;
- commits or rolls back the transaction when exiting the outermost block.

You can disable the creation of savepoints for inner blocks by setting the `savepoint` argument to `False`. If an exception occurs, Django will perform the rollback when exiting the first parent block with a savepoint if there is one, and the outermost block otherwise. Atomicity is still guaranteed by the outer transaction. This option should only be used if the overhead of savepoints is noticeable. It has the drawback of breaking the error handling described above.

You may use `atomic` when autocommit is turned off. It will only use savepoints, even for the outermost block.

---

### Performance considerations

Open transactions have a performance cost for your database server. To minimize this overhead, keep your transactions as short as possible. This is especially important if you're using `atomic()` in long-running processes, outside of Django's request / response cycle.

---

## Autocommit

### Why Django uses autocommit

In the SQL standards, each SQL query starts a transaction, unless one is already active. Such transactions must then be explicitly committed or rolled back.

This isn't always convenient for application developers. To alleviate this problem, most databases provide an auto-commit mode. When autocommit is turned on and no transaction is active, each SQL query gets wrapped in its own

transaction. In other words, not only does each such query start a transaction, but the transaction also gets automatically committed or rolled back, depending on whether the query succeeded.

[PEP 249](#), the Python Database API Specification v2.0, requires autocommit to be initially turned off. Django overrides this default and turns autocommit on.

To avoid this, you can *deactivate the transaction management*, but it isn't recommended.

## Deactivating transaction management

You can totally disable Django's transaction management for a given database by setting `AUTOCOMMIT` to `False` in its configuration. If you do this, Django won't enable autocommit, and won't perform any commits. You'll get the regular behavior of the underlying database library.

This requires you to commit explicitly every transaction, even those started by Django or by third-party libraries. Thus, this is best used in situations where you want to run your own transaction-controlling middleware or do something really strange.

## Performing actions after commit

Sometimes you need to perform an action related to the current database transaction, but only if the transaction successfully commits. Examples might include a [Celery](#) task, an email notification, or a cache invalidation.

Django provides the `on_commit()` function to register callback functions that should be executed after a transaction is successfully committed:

`on_commit` (*func*, *using=None*)

Pass any function (that takes no arguments) to `on_commit()`:

```
from django.db import transaction

def do_something():
    pass # send a mail, invalidate a cache, fire off a Celery task, etc.

transaction.on_commit(do_something)
```

You can also wrap your function in a lambda:

```
transaction.on_commit(lambda: some_celery_task.delay('arg1'))
```

The function you pass in will be called immediately after a hypothetical database write made where `on_commit()` is called would be successfully committed.

If you call `on_commit()` while there isn't an active transaction, the callback will be executed immediately.

If that hypothetical database write is instead rolled back (typically when an unhandled exception is raised in an `atomic()` block), your function will be discarded and never called.

## Savepoints

Savepoints (i.e. nested `atomic()` blocks) are handled correctly. That is, an `on_commit()` callable registered after a savepoint (in a nested `atomic()` block) will be called after the outer transaction is committed, but not if a rollback to that savepoint or any previous savepoint occurred during the transaction:

```

with transaction.atomic(): # Outer atomic, start a new transaction
    transaction.on_commit(foo)

    with transaction.atomic(): # Inner atomic block, create a savepoint
        transaction.on_commit(bar)

# foo() and then bar() will be called when leaving the outermost block

```

On the other hand, when a savepoint is rolled back (due to an exception being raised), the inner callable will not be called:

```

with transaction.atomic(): # Outer atomic, start a new transaction
    transaction.on_commit(foo)

    try:
        with transaction.atomic(): # Inner atomic block, create a savepoint
            transaction.on_commit(bar)
            raise SomeError() # Raising an exception - abort the savepoint
    except SomeError:
        pass

# foo() will be called, but not bar()

```

## Order of execution

On-commit functions for a given transaction are executed in the order they were registered.

## Exception handling

If one on-commit function within a given transaction raises an uncaught exception, no later registered functions in that same transaction will run. This is, of course, the same behavior as if you'd executed the functions sequentially yourself without `on_commit()`.

## Timing of execution

Your callbacks are executed *after* a successful commit, so a failure in a callback will not cause the transaction to roll back. They are executed conditionally upon the success of the transaction, but they are not *part* of the transaction. For the intended use cases (mail notifications, Celery tasks, etc.), this should be fine. If it's not (if your follow-up action is so critical that its failure should mean the failure of the transaction itself), then you don't want to use the `on_commit()` hook. Instead, you may want two-phase commit such as the [psycopg Two-Phase Commit protocol support](#) and the optional [Two-Phase Commit Extensions](#) in the [Python DB-API specification](#).

Callbacks are not run until autocommit is restored on the connection following the commit (because otherwise any queries done in a callback would open an implicit transaction, preventing the connection from going back into autocommit mode).

When in autocommit mode and outside of an `atomic()` block, the function will run immediately, not on commit.

On-commit functions only work with *autocommit mode* and the `atomic()` (or `ATOMIC_REQUESTS`) transaction API. Calling `on_commit()` when autocommit is disabled and you are not within an atomic block will result in an error.

## Use in tests

Django's `TestCase` class wraps each test in a transaction and rolls back that transaction after each test, in order to provide test isolation. This means that no transaction is ever actually committed, thus your `on_commit()` callbacks will never be run. If you need to test the results of an `on_commit()` callback, use a `TransactionTestCase` instead.

## Why no rollback hook?

A rollback hook is harder to implement robustly than a commit hook, since a variety of things can cause an implicit rollback.

For instance, if your database connection is dropped because your process was killed without a chance to shut down gracefully, your rollback hook will never run.

The solution is simple: instead of doing something during the atomic block (transaction) and then undoing it if the transaction fails, use `on_commit()` to delay doing it in the first place until after the transaction succeeds. It's a lot easier to undo something you never did in the first place!

## Low-level APIs

**Warning:** Always prefer `atomic()` if possible at all. It accounts for the idiosyncrasies of each database and prevents invalid operations.

The low level APIs are only useful if you're implementing your own transaction management.

## Autocommit

Django provides a straightforward API in the `django.db.transaction` module to manage the autocommit state of each database connection.

`get_autocommit(using=None)`

`set_autocommit(autocommit, using=None)`

These functions take a `using` argument which should be the name of a database. If it isn't provided, Django uses the "default" database.

Autocommit is initially turned on. If you turn it off, it's your responsibility to restore it.

Once you turn autocommit off, you get the default behavior of your database adapter, and Django won't help you. Although that behavior is specified in [PEP 249](#), implementations of adapters aren't always consistent with one another. Review the documentation of the adapter you're using carefully.

You must ensure that no transaction is active, usually by issuing a `commit()` or a `rollback()`, before turning autocommit back on.

Django will refuse to turn autocommit off when an `atomic()` block is active, because that would break atomicity.

## Transactions

A transaction is an atomic set of database queries. Even if your program crashes, the database guarantees that either all the changes will be applied, or none of them.

Django doesn't provide an API to start a transaction. The expected way to start a transaction is to disable autocommit with `set_autocommit()`.

Once you're in a transaction, you can choose either to apply the changes you've performed until this point with `commit()`, or to cancel them with `rollback()`. These functions are defined in `django.db.transaction`.

**commit** (*using=None*)

**rollback** (*using=None*)

These functions take a `using` argument which should be the name of a database. If it isn't provided, Django uses the "default" database.

Django will refuse to commit or to rollback when an `atomic()` block is active, because that would break atomicity.

## Savepoints

A savepoint is a marker within a transaction that enables you to roll back part of a transaction, rather than the full transaction. Savepoints are available with the SQLite ( $\geq 3.6.8$ ), PostgreSQL, Oracle and MySQL (when using the InnoDB storage engine) backends. Other backends provide the savepoint functions, but they're empty operations – they don't actually do anything.

Savepoints aren't especially useful if you are using autocommit, the default behavior of Django. However, once you open a transaction with `atomic()`, you build up a series of database operations awaiting a commit or rollback. If you issue a rollback, the entire transaction is rolled back. Savepoints provide the ability to perform a fine-grained rollback, rather than the full rollback that would be performed by `transaction.rollback()`.

When the `atomic()` decorator is nested, it creates a savepoint to allow partial commit or rollback. You're strongly encouraged to use `atomic()` rather than the functions described below, but they're still part of the public API, and there's no plan to deprecate them.

Each of these functions takes a `using` argument which should be the name of a database for which the behavior applies. If no `using` argument is provided then the "default" database is used.

Savepoints are controlled by three functions in `django.db.transaction`:

**savepoint** (*using=None*)

Creates a new savepoint. This marks a point in the transaction that is known to be in a "good" state. Returns the savepoint ID (`sid`).

**savepoint\_commit** (*sid, using=None*)

Releases savepoint `sid`. The changes performed since the savepoint was created become part of the transaction.

**savepoint\_rollback** (*sid, using=None*)

Rolls back the transaction to savepoint `sid`.

These functions do nothing if savepoints aren't supported or if the database is in autocommit mode.

In addition, there's a utility function:

**clean\_savepoints** (*using=None*)

Resets the counter used to generate unique savepoint IDs.

The following example demonstrates the use of savepoints:

```
from django.db import transaction

# open a transaction
@transaction.atomic
def viewfunc(request):
```

```
a.save()
# transaction now contains a.save()

sid = transaction.savepoint()

b.save()
# transaction now contains a.save() and b.save()

if want_to_keep_b:
    transaction.savepoint_commit(sid)
    # open transaction still contains a.save() and b.save()
else:
    transaction.savepoint_rollback(sid)
    # open transaction now contains only a.save()
```

Savepoints may be used to recover from a database error by performing a partial rollback. If you're doing this inside an `atomic()` block, the entire block will still be rolled back, because it doesn't know you've handled the situation at a lower level! To prevent this, you can control the rollback behavior with the following functions.

**get\_rollback** (*using=None*)

**set\_rollback** (*rollback, using=None*)

Setting the rollback flag to `True` forces a rollback when exiting the innermost atomic block. This may be useful to trigger a rollback without raising an exception.

Setting it to `False` prevents such a rollback. Before doing that, make sure you've rolled back the transaction to a known-good savepoint within the current atomic block! Otherwise you're breaking atomicity and data corruption may occur.

## Database-specific notes

### Savepoints in SQLite

While SQLite  $\geq$  3.6.8 supports savepoints, a flaw in the design of the `sqlite3` module makes them hardly usable.

When autocommit is enabled, savepoints don't make sense. When it's disabled, `sqlite3` commits implicitly before savepoint statements. (In fact, it commits before any statement other than `SELECT`, `INSERT`, `UPDATE`, `DELETE` and `REPLACE`.) This bug has two consequences:

- The low level APIs for savepoints are only usable inside a transaction ie. inside an `atomic()` block.
- It's impossible to use `atomic()` when autocommit is turned off.

### Transactions in MySQL

If you're using MySQL, your tables may or may not support transactions; it depends on your MySQL version and the table types you're using. (By "table types," we mean something like "InnoDB" or "MyISAM".) MySQL transaction peculiarities are outside the scope of this article, but the MySQL site has [information on MySQL transactions](#).

If your MySQL setup does *not* support transactions, then Django will always function in autocommit mode: statements will be executed and committed as soon as they're called. If your MySQL setup *does* support transactions, Django will handle transactions as explained in this document.

## Handling exceptions within PostgreSQL transactions

**Note:** This section is relevant only if you’re implementing your own transaction management. This problem cannot occur in Django’s default mode and `atomic()` handles it automatically.

Inside a transaction, when a call to a PostgreSQL cursor raises an exception (typically `IntegrityError`), all subsequent SQL in the same transaction will fail with the error “current transaction is aborted, queries ignored until end of transaction block”. While simple use of `save()` is unlikely to raise an exception in PostgreSQL, there are more advanced usage patterns which might, such as saving objects with unique fields, saving using the `force_insert/force_update` flag, or invoking custom SQL.

There are several ways to recover from this sort of error.

### Transaction rollback

The first option is to roll back the entire transaction. For example:

```
a.save() # Succeeds, but may be undone by transaction rollback
try:
    b.save() # Could throw exception
except IntegrityError:
    transaction.rollback()
c.save() # Succeeds, but a.save() may have been undone
```

Calling `transaction.rollback()` rolls back the entire transaction. Any uncommitted database operations will be lost. In this example, the changes made by `a.save()` would be lost, even though that operation raised no error itself.

### Savepoint rollback

You can use *savepoints* to control the extent of a rollback. Before performing a database operation that could fail, you can set or update the savepoint; that way, if the operation fails, you can roll back the single offending operation, rather than the entire transaction. For example:

```
a.save() # Succeeds, and never undone by savepoint rollback
sid = transaction.savepoint()
try:
    b.save() # Could throw exception
    transaction.savepoint_commit(sid)
except IntegrityError:
    transaction.savepoint_rollback(sid)
c.save() # Succeeds, and a.save() is never undone
```

In this example, `a.save()` will not be undone in the case where `b.save()` raises an exception.

## 3.2.8 Multiple databases

This topic guide describes Django’s support for interacting with multiple databases. Most of the rest of Django’s documentation assumes you are interacting with a single database. If you want to interact with multiple databases, you’ll need to take some additional steps.

## Defining your databases

The first step to using more than one database with Django is to tell Django about the database servers you'll be using. This is done using the `DATABASES` setting. This setting maps database aliases, which are a way to refer to a specific database throughout Django, to a dictionary of settings for that specific connection. The settings in the inner dictionaries are described fully in the `DATABASES` documentation.

Databases can have any alias you choose. However, the alias `default` has special significance. Django uses the database with the alias of `default` when no other database has been selected.

The following is an example `settings.py` snippet defining two databases – a default PostgreSQL database and a MySQL database called `users`:

```
DATABASES = {
    'default': {
        'NAME': 'app_data',
        'ENGINE': 'django.db.backends.postgresql',
        'USER': 'postgres_user',
        'PASSWORD': 's3krit'
    },
    'users': {
        'NAME': 'user_data',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'priv4te'
    }
}
```

If the concept of a `default` database doesn't make sense in the context of your project, you need to be careful to always specify the database that you want to use. Django requires that a `default` database entry be defined, but the parameters dictionary can be left blank if it will not be used. To do this, you must set up `DATABASE_ROUTERS` for all of your apps' models, including those in any contrib and third-party apps you're using, so that no queries are routed to the default database. The following is an example `settings.py` snippet defining two non-default databases, with the `default` entry intentionally left empty:

```
DATABASES = {
    'default': {},
    'users': {
        'NAME': 'user_data',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'superS3cret'
    },
    'customers': {
        'NAME': 'customer_data',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_cust',
        'PASSWORD': 'veryPriv@ate'
    }
}
```

If you attempt to access a database that you haven't defined in your `DATABASES` setting, Django will raise a `django.db.utils.ConnectionDoesNotExist` exception.

## Synchronizing your databases

The `migrate` management command operates on one database at a time. By default, it operates on the `default` database, but by providing the `--database` option, you can tell it to synchronize a different database. So, to synchronize all models onto all databases in the first example above, you would need to call:

```
$ ./manage.py migrate
$ ./manage.py migrate --database=users
```

If you don't want every application to be synchronized onto a particular database, you can define a *database router* that implements a policy constraining the availability of particular models.

If, as in the second example above, you've left the `default` database empty, you must provide a database name each time you run `migrate`. Omitting the database name would raise an error. For the second example:

```
$ ./manage.py migrate --database=users
$ ./manage.py migrate --database=customers
```

## Using other management commands

Most other `django-admin` commands that interact with the database operate in the same way as `migrate` – they only ever operate on one database at a time, using `--database` to control the database used.

An exception to this rule is the `makemigrations` command. It validates the migration history in the databases to catch problems with the existing migration files (which could be caused by editing them) before creating new migrations. By default, it checks only the `default` database, but it consults the `allow_migrate()` method of *routers* if any are installed.

Migration consistency checks were added. Checks based on database routers were added in 1.10.1.

## Automatic database routing

The easiest way to use multiple databases is to set up a database routing scheme. The default routing scheme ensures that objects remain 'sticky' to their original database (i.e., an object retrieved from the `foo` database will be saved on the same database). The default routing scheme ensures that if a database isn't specified, all queries fall back to the `default` database.

You don't have to do anything to activate the default routing scheme – it is provided 'out of the box' on every Django project. However, if you want to implement more interesting database allocation behaviors, you can define and install your own database routers.

## Database routers

A database Router is a class that provides up to four methods:

**`db_for_read(model, **hints)`**

Suggest the database that should be used for read operations for objects of type `model`.

If a database operation is able to provide any additional information that might assist in selecting a database, it will be provided in the `hints` dictionary. Details on valid hints are provided *below*.

Returns `None` if there is no suggestion.

**`db_for_write(model, **hints)`**

Suggest the database that should be used for writes of objects of type `Model`.

If a database operation is able to provide any additional information that might assist in selecting a database, it will be provided in the `hints` dictionary. Details on valid hints are provided *below*.

Returns `None` if there is no suggestion.

**`allow_relation`** (*obj1, obj2, \*\*hints*)

Return `True` if a relation between `obj1` and `obj2` should be allowed, `False` if the relation should be prevented, or `None` if the router has no opinion. This is purely a validation operation, used by foreign key and many to many operations to determine if a relation should be allowed between two objects.

**`allow_migrate`** (*db, app\_label, model\_name=None, \*\*hints*)

Determine if the migration operation is allowed to run on the database with alias `db`. Return `True` if the operation should run, `False` if it shouldn't run, or `None` if the router has no opinion.

The `app_label` positional argument is the label of the application being migrated.

`model_name` is set by most migration operations to the value of `model._meta.model_name` (the lower-cased version of the model `__name__`) of the model being migrated. Its value is `None` for the *RunPython* and *RunSQL* operations unless they provide it using hints.

`hints` are used by certain operations to communicate additional information to the router.

When `model_name` is set, `hints` normally contains the model class under the key `'model'`. Note that it may be a *historical model*, and thus not have any custom attributes, methods, or managers. You should only rely on `_meta`.

This method can also be used to determine the availability of a model on a given database.

*makemigrations* always creates migrations for model changes, but if `allow_migrate()` returns `False`, any migration operations for the `model_name` will be silently skipped when running *migrate* on the `db`. Changing the behavior of `allow_migrate()` for models that already have migrations may result in broken foreign keys, extra tables, or missing tables. When *makemigrations* verifies the migration history, it skips databases where no app is allowed to migrate.

A router doesn't have to provide *all* these methods – it may omit one or more of them. If one of the methods is omitted, Django will skip that router when performing the relevant check.

## Hints

The hints received by the database router can be used to decide which database should receive a given request.

At present, the only hint that will be provided is `instance`, an object instance that is related to the read or write operation that is underway. This might be the instance that is being saved, or it might be an instance that is being added in a many-to-many relation. In some cases, no instance hint will be provided at all. The router checks for the existence of an instance hint, and determine if that hint should be used to alter routing behavior.

## Using routers

Database routers are installed using the `DATABASE_ROUTERS` setting. This setting defines a list of class names, each specifying a router that should be used by the master router (`django.db.router`).

The master router is used by Django's database operations to allocate database usage. Whenever a query needs to know which database to use, it calls the master router, providing a model and a hint (if available). Django then tries each router in turn until a database suggestion can be found. If no suggestion can be found, it tries the current `_state.db` of the hint instance. If a hint instance wasn't provided, or the instance doesn't currently have database state, the master router will allocate the `default` database.

## An example

### Example purposes only!

This example is intended as a demonstration of how the router infrastructure can be used to alter database usage. It intentionally ignores some complex issues in order to demonstrate how routers are used.

This example won't work if any of the models in `myapp` contain relationships to models outside of the other database. *Cross-database relationships* introduce referential integrity problems that Django can't currently handle.

The primary/replica (referred to as master/slave by some databases) configuration described is also flawed – it doesn't provide any solution for handling replication lag (i.e., query inconsistencies introduced because of the time taken for a write to propagate to the replicas). It also doesn't consider the interaction of transactions with the database utilization strategy.

So - what does this mean in practice? Let's consider another sample configuration. This one will have several databases: one for the `auth` application, and all other apps using a primary/replica setup with two read replicas. Here are the settings specifying these databases:

```
DATABASES = {
    'default': {},
    'auth_db': {
        'NAME': 'auth_db',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'swordfish',
    },
    'primary': {
        'NAME': 'primary',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'spam',
    },
    'replica1': {
        'NAME': 'replica1',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'eggs',
    },
    'replica2': {
        'NAME': 'replica2',
        'ENGINE': 'django.db.backends.mysql',
        'USER': 'mysql_user',
        'PASSWORD': 'bacon',
    },
}
```

Now we'll need to handle routing. First we want a router that knows to send queries for the `auth` app to `auth_db`:

```
class AuthRouter(object):
    """
    A router to control all database operations on models in the
    auth application.
    """
    def db_for_read(self, model, **hints):
        """
        Attempts to read auth models go to auth_db.
        """
```

```
"""
    if model._meta.app_label == 'auth':
        return 'auth_db'
    return None

def db_for_write(self, model, **hints):
    """
    Attempts to write auth models go to auth_db.
    """
    if model._meta.app_label == 'auth':
        return 'auth_db'
    return None

def allow_relation(self, obj1, obj2, **hints):
    """
    Allow relations if a model in the auth app is involved.
    """
    if obj1._meta.app_label == 'auth' or \
        obj2._meta.app_label == 'auth':
        return True
    return None

def allow_migrate(self, db, app_label, model_name=None, **hints):
    """
    Make sure the auth app only appears in the 'auth_db'
    database.
    """
    if app_label == 'auth':
        return db == 'auth_db'
    return None
```

And we also want a router that sends all other apps to the primary/replica configuration, and randomly chooses a replica to read from:

```
import random

class PrimaryReplicaRouter(object):
    def db_for_read(self, model, **hints):
        """
        Reads go to a randomly-chosen replica.
        """
        return random.choice(['replica1', 'replica2'])

    def db_for_write(self, model, **hints):
        """
        Writes always go to primary.
        """
        return 'primary'

    def allow_relation(self, obj1, obj2, **hints):
        """
        Relations between objects are allowed if both objects are
        in the primary/replica pool.
        """
        db_list = ('primary', 'replica1', 'replica2')
        if obj1._state.db in db_list and obj2._state.db in db_list:
            return True
        return None
```

```
def allow_migrate(self, db, app_label, model_name=None, **hints):
    """
    All non-auth models end up in this pool.
    """
    return True
```

Finally, in the settings file, we add the following (substituting `path.to.` with the actual Python path to the module(s) where the routers are defined):

```
DATABASE_ROUTERS = ['path.to.AuthRouter', 'path.to.PrimaryReplicaRouter']
```

The order in which routers are processed is significant. Routers will be queried in the order they are listed in the `DATABASE_ROUTERS` setting. In this example, the `AuthRouter` is processed before the `PrimaryReplicaRouter`, and as a result, decisions concerning the models in `auth` are processed before any other decision is made. If the `DATABASE_ROUTERS` setting listed the two routers in the other order, `PrimaryReplicaRouter.allow_migrate()` would be processed first. The catch-all nature of the `PrimaryReplicaRouter` implementation would mean that all models would be available on all databases.

With this setup installed, lets run some Django code:

```
>>> # This retrieval will be performed on the 'auth_db' database
>>> fred = User.objects.get(username='fred')
>>> fred.first_name = 'Frederick'

>>> # This save will also be directed to 'auth_db'
>>> fred.save()

>>> # These retrieval will be randomly allocated to a replica database
>>> dna = Person.objects.get(name='Douglas Adams')

>>> # A new object has no database allocation when created
>>> mh = Book(title='Mostly Harmless')

>>> # This assignment will consult the router, and set mh onto
>>> # the same database as the author object
>>> mh.author = dna

>>> # This save will force the 'mh' instance onto the primary database...
>>> mh.save()

>>> # ... but if we re-retrieve the object, it will come back on a replica
>>> mh = Book.objects.get(title='Mostly Harmless')
```

This example defined a router to handle interaction with models from the `auth` app, and other routers to handle interaction with all other apps. If you left your default database empty and don't want to define a catch-all database router to handle all apps not otherwise specified, your routers must handle the names of all apps in `INSTALLED_APPS` before you migrate. See *Behavior of contrib apps* for information about contrib apps that must be together in one database.

### Manually selecting a database

Django also provides an API that allows you to maintain complete control over database usage in your code. A manually specified database allocation will take priority over a database allocated by a router.

## Manually selecting a database for a QuerySet

You can select the database for a QuerySet at any point in the QuerySet “chain.” Just call `using()` on the QuerySet to get another QuerySet that uses the specified database.

`using()` takes a single argument: the alias of the database on which you want to run the query. For example:

```
>>> # This will run on the 'default' database.
>>> Author.objects.all()

>>> # So will this.
>>> Author.objects.using('default').all()

>>> # This will run on the 'other' database.
>>> Author.objects.using('other').all()
```

## Selecting a database for `save()`

Use the `using` keyword to `Model.save()` to specify to which database the data should be saved.

For example, to save an object to the `legacy_users` database, you’d use this:

```
>>> my_object.save(using='legacy_users')
```

If you don’t specify `using`, the `save()` method will save into the default database allocated by the routers.

## Moving an object from one database to another

If you’ve saved an instance to one database, it might be tempting to use `save(using=...)` as a way to migrate the instance to a new database. However, if you don’t take appropriate steps, this could have some unexpected consequences.

Consider the following example:

```
>>> p = Person(name='Fred')
>>> p.save(using='first') # (statement 1)
>>> p.save(using='second') # (statement 2)
```

In statement 1, a new `Person` object is saved to the `first` database. At this time, `p` doesn’t have a primary key, so Django issues an SQL `INSERT` statement. This creates a primary key, and Django assigns that primary key to `p`.

When the save occurs in statement 2, `p` already has a primary key value, and Django will attempt to use that primary key on the new database. If the primary key value isn’t in use in the `second` database, then you won’t have any problems – the object will be copied to the new database.

However, if the primary key of `p` is already in use on the `second` database, the existing object in the `second` database will be overridden when `p` is saved.

You can avoid this in two ways. First, you can clear the primary key of the instance. If an object has no primary key, Django will treat it as a new object, avoiding any loss of data on the `second` database:

```
>>> p = Person(name='Fred')
>>> p.save(using='first')
>>> p.pk = None # Clear the primary key.
>>> p.save(using='second') # Write a completely new object.
```

The second option is to use the `force_insert` option to `save()` to ensure that Django does an SQL `INSERT`:

```
>>> p = Person(name='Fred')
>>> p.save(using='first')
>>> p.save(using='second', force_insert=True)
```

This will ensure that the person named `Fred` will have the same primary key on both databases. If that primary key is already in use when you try to save onto the `second` database, an error will be raised.

### Selecting a database to delete from

By default, a call to delete an existing object will be executed on the same database that was used to retrieve the object in the first place:

```
>>> u = User.objects.using('legacy_users').get(username='fred')
>>> u.delete() # will delete from the `legacy_users` database
```

To specify the database from which a model will be deleted, pass a `using` keyword argument to the `Model.delete()` method. This argument works just like the `using` keyword argument to `save()`.

For example, if you're migrating a user from the `legacy_users` database to the `new_users` database, you might use these commands:

```
>>> user_obj.save(using='new_users')
>>> user_obj.delete(using='legacy_users')
```

### Using managers with multiple databases

Use the `db_manager()` method on managers to give managers access to a non-default database.

For example, say you have a custom manager method that touches the database – `User.objects.create_user()`. Because `create_user()` is a manager method, not a `QuerySet` method, you can't do `User.objects.using('new_users').create_user()`. (The `create_user()` method is only available on `User.objects`, the manager, not on `QuerySet` objects derived from the manager.) The solution is to use `db_manager()`, like this:

```
User.objects.db_manager('new_users').create_user(...)
```

`db_manager()` returns a copy of the manager bound to the database you specify.

### Using `get_queryset()` with multiple databases

If you're overriding `get_queryset()` on your manager, be sure to either call the method on the parent (using `super()`) or do the appropriate handling of the `_db` attribute on the manager (a string containing the name of the database to use).

For example, if you want to return a custom `QuerySet` class from the `get_queryset` method, you could do this:

```
class MyManager(models.Manager):
    def get_queryset(self):
        qs = CustomQuerySet(self.model)
        if self._db is not None:
            qs = qs.using(self._db)
        return qs
```

## Exposing multiple databases in Django's admin interface

Django's admin doesn't have any explicit support for multiple databases. If you want to provide an admin interface for a model on a database other than that specified by your router chain, you'll need to write custom `ModelAdmin` classes that will direct the admin to use a specific database for content.

`ModelAdmin` objects have five methods that require customization for multiple-database support:

```
class MultiDBModelAdmin(admin.ModelAdmin):
    # A handy constant for the name of the alternate database.
    using = 'other'

    def save_model(self, request, obj, form, change):
        # Tell Django to save objects to the 'other' database.
        obj.save(using=self.using)

    def delete_model(self, request, obj):
        # Tell Django to delete objects from the 'other' database
        obj.delete(using=self.using)

    def get_queryset(self, request):
        # Tell Django to look for objects on the 'other' database.
        return super(MultiDBModelAdmin, self).get_queryset(request).using(self.using)

    def formfield_for_foreignkey(self, db_field, request, **kwargs):
        # Tell Django to populate ForeignKey widgets using a query
        # on the 'other' database.
        return super(MultiDBModelAdmin, self).formfield_for_foreignkey(db_field,
↪request, using=self.using, **kwargs)

    def formfield_for_manytomany(self, db_field, request, **kwargs):
        # Tell Django to populate ManyToMany widgets using a query
        # on the 'other' database.
        return super(MultiDBModelAdmin, self).formfield_for_manytomany(db_field,
↪request, using=self.using, **kwargs)
```

The implementation provided here implements a multi-database strategy where all objects of a given type are stored on a specific database (e.g., all `User` objects are in the `other` database). If your usage of multiple databases is more complex, your `ModelAdmin` will need to reflect that strategy.

`InlineModelAdmin` objects can be handled in a similar fashion. They require three customized methods:

```
class MultiDBTabularInline(admin.TabularInline):
    using = 'other'

    def get_queryset(self, request):
        # Tell Django to look for inline objects on the 'other' database.
        return super(MultiDBTabularInline, self).get_queryset(request).using(self.
↪using)

    def formfield_for_foreignkey(self, db_field, request, **kwargs):
        # Tell Django to populate ForeignKey widgets using a query
        # on the 'other' database.
        return super(MultiDBTabularInline, self).formfield_for_foreignkey(db_field,
↪request, using=self.using, **kwargs)

    def formfield_for_manytomany(self, db_field, request, **kwargs):
        # Tell Django to populate ManyToMany widgets using a query
        # on the 'other' database.
```

```

return super(MultiDBTabularInline, self).formfield_for_manytomany(db_field,
↳request, using=self.using, **kwargs)

```

Once you’ve written your model admin definitions, they can be registered with any Admin instance:

```

from django.contrib import admin

# Specialize the multi-db admin objects for use with specific models.
class BookInline(MultiDBTabularInline):
    model = Book

class PublisherAdmin(MultiDBModelAdmin):
    inlines = [BookInline]

admin.site.register(Author, MultiDBModelAdmin)
admin.site.register(Publisher, PublisherAdmin)

othersite = admin.AdminSite('othersite')
othersite.register(Publisher, MultiDBModelAdmin)

```

This example sets up two admin sites. On the first site, the Author and Publisher objects are exposed; Publisher objects have an tabular inline showing books published by that publisher. The second site exposes just publishers, without the inlines.

## Using raw cursors with multiple databases

If you are using more than one database you can use `django.db.connections` to obtain the connection (and cursor) for a specific database. `django.db.connections` is a dictionary-like object that allows you to retrieve a specific connection using its alias:

```

from django.db import connections
cursor = connections['my_db_alias'].cursor()

```

## Limitations of multiple databases

### Cross-database relations

Django doesn’t currently provide any support for foreign key or many-to-many relationships spanning multiple databases. If you have used a router to partition models to different databases, any foreign key and many-to-many relationships defined by those models must be internal to a single database.

This is because of referential integrity. In order to maintain a relationship between two objects, Django needs to know that the primary key of the related object is valid. If the primary key is stored on a separate database, it’s not possible to easily evaluate the validity of a primary key.

If you’re using Postgres, Oracle, or MySQL with InnoDB, this is enforced at the database integrity level – database level key constraints prevent the creation of relations that can’t be validated.

However, if you’re using SQLite or MySQL with MyISAM tables, there is no enforced referential integrity; as a result, you may be able to ‘fake’ cross database foreign keys. However, this configuration is not officially supported by Django.

## Behavior of contrib apps

Several contrib apps include models, and some apps depend on others. Since cross-database relationships are impossible, this creates some restrictions on how you can split these models across databases:

- each one of `contenttypes.ContentType`, `sessions.Session` and `sites.Site` can be stored in any database, given a suitable router.
- auth models — `User`, `Group` and `Permission` — are linked together and linked to `ContentType`, so they must be stored in the same database as `ContentType`.
- `admin` depends on `auth`, so its models must be in the same database as `auth`.
- `flatpages` and `redirects` depend on `sites`, so their models must be in the same database as `sites`.

In addition, some objects are automatically created just after `migrate` creates a table to hold them in a database:

- a default `Site`,
- a `ContentType` for each model (including those not stored in that database),
- three `Permission` for each model (including those not stored in that database).

For common setups with multiple databases, it isn't useful to have these objects in more than one database. Common setups include primary/replica and connecting to external databases. Therefore, it's recommended to write a `database router` that allows synchronizing these three models to only one database. Use the same approach for contrib and third-party apps that don't need their tables in multiple databases.

**Warning:** If you're synchronizing content types to more than one database, be aware that their primary keys may not match across databases. This may result in data corruption or data loss.

## 3.2.9 Tablespaces

A common paradigm for optimizing performance in database systems is the use of `tablespaces` to organize disk layout.

**Warning:** Django does not create the tablespaces for you. Please refer to your database engine's documentation for details on creating and managing tablespaces.

### Declaring tablespaces for tables

A tablespace can be specified for the table generated by a model by supplying the `db_tablespace` option inside the model's `class Meta`. This option also affects tables automatically created for `ManyToManyFields` in the model.

You can use the `DEFAULT_TABLESPACE` setting to specify a default value for `db_tablespace`. This is useful for setting a tablespace for the built-in Django apps and other applications whose code you cannot control.

### Declaring tablespaces for indexes

You can pass the `db_tablespace` option to a `Field` constructor to specify an alternate tablespace for the `Field`'s column index. If no index would be created for the column, the option is ignored.

You can use the `DEFAULT_INDEX_TABLESPACE` setting to specify a default value for `db_tablespace`.

If `db_tablespace` isn't specified and you didn't set `DEFAULT_INDEX_TABLESPACE`, the index is created in the same tablespace as the tables.

### An example

```
class TablespaceExample(models.Model):
    name = models.CharField(max_length=30, db_index=True, db_tablespace="indexes")
    data = models.CharField(max_length=255, db_index=True)
    edges = models.ManyToManyField(to="self", db_tablespace="indexes")

    class Meta:
        db_tablespace = "tables"
```

In this example, the tables generated by the `TablespaceExample` model (i.e. the model table and the many-to-many table) would be stored in the `tables` tablespace. The index for the `name` field and the indexes on the many-to-many table would be stored in the `indexes` tablespace. The `data` field would also generate an index, but no tablespace for it is specified, so it would be stored in the model tablespace `tables` by default.

### Database support

PostgreSQL and Oracle support tablespaces. SQLite and MySQL don't.

When you use a backend that lacks support for tablespaces, Django ignores all tablespace-related options.

## 3.2.10 Database access optimization

Django's database layer provides various ways to help developers get the most out of their databases. This document gathers together links to the relevant documentation, and adds various tips, organized under a number of headings that outline the steps to take when attempting to optimize your database usage.

### Profile first

As general programming practice, this goes without saying. Find out *what queries you are doing and what they are costing you*. You may also want to use an external project like `django-debug-toolbar`, or a tool that monitors your database directly.

Remember that you may be optimizing for speed or memory or both, depending on your requirements. Sometimes optimizing for one will be detrimental to the other, but sometimes they will help each other. Also, work that is done by the database process might not have the same cost (to you) as the same amount of work done in your Python process. It is up to you to decide what your priorities are, where the balance must lie, and profile all of these as required since this will depend on your application and server.

With everything that follows, remember to profile after every change to ensure that the change is a benefit, and a big enough benefit given the decrease in readability of your code. **All** of the suggestions below come with the caveat that in your circumstances the general principle might not apply, or might even be reversed.

### Use standard DB optimization techniques

...including:

- **Indexes.** This is a number one priority, *after* you have determined from profiling what indexes should be added. Use `Field.db_index` or `Meta.index_together` to add these from Django. Consider adding indexes to fields that you frequently query using `filter()`, `exclude()`, `order_by()`, etc. as indexes may help to speed up lookups. Note that determining the best indexes is a complex database-dependent topic that will depend on your particular application. The overhead of maintaining an index may outweigh any gains in query speed.
- Appropriate use of field types.

We will assume you have done the obvious things above. The rest of this document focuses on how to use Django in such a way that you are not doing unnecessary work. This document also does not address other optimization techniques that apply to all expensive operations, such as *general purpose caching*.

## Understand QuerySets

Understanding *QuerySets* is vital to getting good performance with simple code. In particular:

### Understand QuerySet evaluation

To avoid performance problems, it is important to understand:

- that *QuerySets are lazy*.
- when *they are evaluated*.
- how *the data is held in memory*.

### Understand cached attributes

As well as caching of the whole `QuerySet`, there is caching of the result of attributes on ORM objects. In general, attributes that are not callable will be cached. For example, assuming the *example Weblog models*:

```
>>> entry = Entry.objects.get(id=1)
>>> entry.blog # Blog object is retrieved at this point
>>> entry.blog # cached version, no DB access
```

But in general, callable attributes cause DB lookups every time:

```
>>> entry = Entry.objects.get(id=1)
>>> entry.authors.all() # query performed
>>> entry.authors.all() # query performed again
```

Be careful when reading template code - the template system does not allow use of parentheses, but will call callables automatically, hiding the above distinction.

Be careful with your own custom properties - it is up to you to implement caching when required, for example using the `cached_property` decorator.

### Use the `with` template tag

To make use of the caching behavior of `QuerySet`, you may need to use the `with` template tag.

## Use `iterator()`

When you have a lot of objects, the caching behavior of the `QuerySet` can cause a large amount of memory to be used. In this case, `iterator()` may help.

## Do database work in the database rather than in Python

For instance:

- At the most basic level, use *filter and exclude* to do filtering in the database.
- Use *F expressions* to filter based on other fields within the same model.
- Use *annotate to do aggregation in the database*.

If these aren't enough to generate the SQL you need:

## Use `RawSQL`

A less portable but more powerful method is the `RawSQL` expression, which allows some SQL to be explicitly added to the query. If that still isn't powerful enough:

## Use raw SQL

Write your own *custom SQL to retrieve data or populate models*. Use `django.db.connection.queries` to find out what Django is writing for you and start from there.

## Retrieve individual objects using a unique, indexed column

There are two reasons to use a column with *unique* or *db\_index* when using `get()` to retrieve individual objects. First, the query will be quicker because of the underlying database index. Also, the query could run much slower if multiple objects match the lookup; having a unique constraint on the column guarantees this will never happen.

So using the *example Weblog models*:

```
>>> entry = Entry.objects.get(id=10)
```

will be quicker than:

```
>>> entry = Entry.objects.get(headline="News Item Title")
```

because `id` is indexed by the database and is guaranteed to be unique.

Doing the following is potentially quite slow:

```
>>> entry = Entry.objects.get(headline__startswith="News")
```

First of all, `headline` is not indexed, which will make the underlying database fetch slower.

Second, the lookup doesn't guarantee that only one object will be returned. If the query matches more than one object, it will retrieve and transfer all of them from the database. This penalty could be substantial if hundreds or thousands of records are returned. The penalty will be compounded if the database lives on a separate server, where network overhead and latency also play a factor.

## Retrieve everything at once if you know you will need it

Hitting the database multiple times for different parts of a single ‘set’ of data that you will need all parts of is, in general, less efficient than retrieving it all in one query. This is particularly important if you have a query that is executed in a loop, and could therefore end up doing many database queries, when only one was needed. So:

### Use `QuerySet.select_related()` and `prefetch_related()`

Understand `select_related()` and `prefetch_related()` thoroughly, and use them:

- in *managers and default managers* where appropriate. Be aware when your manager is and is not used; sometimes this is tricky so don’t make assumptions.
- in view code or other layers, possibly making use of `prefetch_related_objects()` where needed.

## Don’t retrieve things you don’t need

### Use `QuerySet.values()` and `values_list()`

When you just want a `dict` or `list` of values, and don’t need ORM model objects, make appropriate usage of `values()`. These can be useful for replacing model objects in template code - as long as the dicts you supply have the same attributes as those used in the template, you are fine.

### Use `QuerySet.defer()` and `only()`

Use `defer()` and `only()` if there are database columns you know that you won’t need (or won’t need in most cases) to avoid loading them. Note that if you *do* use them, the ORM will have to go and get them in a separate query, making this a pessimization if you use it inappropriately.

Also, be aware that there is some (small extra) overhead incurred inside Django when constructing a model with deferred fields. Don’t be too aggressive in deferring fields without profiling as the database has to read most of the non-text, non-VARCHAR data from the disk for a single row in the results, even if it ends up only using a few columns. The `defer()` and `only()` methods are most useful when you can avoid loading a lot of text data or for fields that might take a lot of processing to convert back to Python. As always, profile first, then optimize.

### Use `QuerySet.count()`

...if you only want the count, rather than doing `len(queryset)`.

### Use `QuerySet.exists()`

...if you only want to find out if at least one result exists, rather than `if queryset`.

But:

## Don’t overuse `count()` and `exists()`

If you are going to need other data from the `QuerySet`, just evaluate it.

For example, assuming an Email model that has a `body` attribute and a many-to-many relation to User, the following template code is optimal:

```
{% if display_inbox %}
  {% with emails=user.emails.all %}
    {% if emails %}
      <p>You have {{ emails|length }} email(s)</p>
      {% for email in emails %}
        <p>{{ email.body }}</p>
      {% endfor %}
    {% else %}
      <p>No messages today.</p>
    {% endif %}
  {% endwith %}
{% endif %}
```

It is optimal because:

1. Since QuerySets are lazy, this does no database queries if 'display\_inbox' is False.
2. Use of `with` means that we store `user.emails.all` in a variable for later use, allowing its cache to be re-used.
3. The line `{% if emails %}` causes `QuerySet.__bool__()` to be called, which causes the `user.emails.all()` query to be run on the database, and at the least the first line to be turned into an ORM object. If there aren't any results, it will return False, otherwise True.
4. The use of `{{ emails|length }}` calls `QuerySet.__len__()`, filling out the rest of the cache without doing another query.
5. The `for` loop iterates over the already filled cache.

In total, this code does either one or zero database queries. The only deliberate optimization performed is the use of the `with` tag. Using `QuerySet.exists()` or `QuerySet.count()` at any point would cause additional queries.

### Use `QuerySet.update()` and `delete()`

Rather than retrieve a load of objects, set some values, and save them individual, use a bulk SQL UPDATE statement, via `QuerySet.update()`. Similarly, do *bulk deletes* where possible.

Note, however, that these bulk update methods cannot call the `save()` or `delete()` methods of individual instances, which means that any custom behavior you have added for these methods will not be executed, including anything driven from the normal database object *signals*.

### Use foreign key values directly

If you only need a foreign key value, use the foreign key value that is already on the object you've got, rather than getting the whole related object and taking its primary key. i.e. do:

```
entry.blog_id
```

instead of:

```
entry.blog.id
```

## Don't order results if you don't care

Ordering is not free; each field to order by is an operation the database must perform. If a model has a default ordering (*Meta.ordering*) and you don't need it, remove it on a `QuerySet` by calling `order_by()` with no parameters.

Adding an index to your database may help to improve ordering performance.

## Insert in bulk

When creating objects, where possible, use the `bulk_create()` method to reduce the number of SQL queries. For example:

```
Entry.objects.bulk_create([
    Entry(headline='This is a test'),
    Entry(headline='This is only a test'),
])
```

...is preferable to:

```
Entry.objects.create(headline='This is a test')
Entry.objects.create(headline='This is only a test')
```

Note that there are a number of *caveats to this method*, so make sure it's appropriate for your use case.

This also applies to *ManyToManyFields*, so doing:

```
my_band.members.add(me, my_friend)
```

...is preferable to:

```
my_band.members.add(me)
my_band.members.add(my_friend)
```

...where `Bands` and `Artists` have a many-to-many relationship.

## 3.2.11 Examples of model relationship API usage

### Many-to-many relationships

To define a many-to-many relationship, use *ManyToManyField*.

In this example, an `Article` can be published in multiple `Publication` objects, and a `Publication` has multiple `Article` objects:

```
from django.db import models

class Publication(models.Model):
    title = models.CharField(max_length=30)

    def __str__(self):
        return self.title

    class Meta:
        ordering = ('title',)

class Article(models.Model):
```

```

headline = models.CharField(max_length=100)
publications = models.ManyToManyField(Publication)

def __str__(self):
    return self.headline

class Meta:
    ordering = ('headline',)

```

What follows are examples of operations that can be performed using the Python API facilities. Note that if you are using *an intermediate model* for a many-to-many relationship, some of the related manager's methods are disabled, so some of these examples won't work with such models.

Create a couple of Publications:

```

>>> p1 = Publication(title='The Python Journal')
>>> p1.save()
>>> p2 = Publication(title='Science News')
>>> p2.save()
>>> p3 = Publication(title='Science Weekly')
>>> p3.save()

```

Create an Article:

```

>>> a1 = Article(headline='Django lets you build Web apps easily')

```

You can't associate it with a Publication until it's been saved:

```

>>> a1.publications.add(p1)
Traceback (most recent call last):
...
ValueError: 'Article' instance needs to have a primary key value before a many-to-
↪many relationship can be used.

```

Save it!

```

>>> a1.save()

```

Associate the Article with a Publication:

```

>>> a1.publications.add(p1)

```

Create another Article, and set it to appear in both Publications:

```

>>> a2 = Article(headline='NASA uses Python')
>>> a2.save()
>>> a2.publications.add(p1, p2)
>>> a2.publications.add(p3)

```

Adding a second time is OK:

```

>>> a2.publications.add(p3)

```

Adding an object of the wrong type raises `TypeError`:

```

>>> a2.publications.add(a1)
Traceback (most recent call last):

```

```
...
TypeError: 'Publication' instance expected
```

Create and add a Publication to an Article in one step using `create()`:

```
>>> new_publication = a2.publications.create(title='Highlights for Children')
```

Article objects have access to their related Publication objects:

```
>>> a1.publications.all()
<QuerySet [<Publication: The Python Journal>]>
>>> a2.publications.all()
<QuerySet [<Publication: Highlights for Children>, <Publication: Science News>,
↳<Publication: Science Weekly>, <Publication: The Python Journal>]>
```

Publication objects have access to their related Article objects:

```
>>> p2.article_set.all()
<QuerySet [<Article: NASA uses Python>]>
>>> p1.article_set.all()
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>
>>> Publication.objects.get(id=4).article_set.all()
<QuerySet [<Article: NASA uses Python>]>
```

Many-to-many relationships can be queried using *lookups across relationships*:

```
>>> Article.objects.filter(publications__id=1)
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>
>>> Article.objects.filter(publications__pk=1)
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>
>>> Article.objects.filter(publications=1)
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>
>>> Article.objects.filter(publications=p1)
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>

>>> Article.objects.filter(publications__title__startswith="Science")
<QuerySet [<Article: NASA uses Python>, <Article: NASA uses Python>]>

>>> Article.objects.filter(publications__title__startswith="Science").distinct()
<QuerySet [<Article: NASA uses Python>]>
```

The `count()` function respects `distinct()` as well:

```
>>> Article.objects.filter(publications__title__startswith="Science").count()
2

>>> Article.objects.filter(publications__title__startswith="Science").distinct().
↳count()
1

>>> Article.objects.filter(publications__in=[1,2]).distinct()
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses
↳Python>]>
```

```
>>> Article.objects.filter(publications__in=[p1,p2]).distinct()
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA uses_
↳Python>]>
```

Reverse m2m queries are supported (i.e., starting at the table that doesn't have a *ManyToManyField*):

```
>>> Publication.objects.filter(id=1)
<QuerySet [<Publication: The Python Journal>]>
>>> Publication.objects.filter(pk=1)
<QuerySet [<Publication: The Python Journal>]>

>>> Publication.objects.filter(article__headline__startswith="NASA")
<QuerySet [<Publication: Highlights for Children>, <Publication: Science News>,
↳<Publication: Science Weekly>, <Publication: The Python Journal>]>

>>> Publication.objects.filter(article__id=1)
<QuerySet [<Publication: The Python Journal>]>
>>> Publication.objects.filter(article__pk=1)
<QuerySet [<Publication: The Python Journal>]>
>>> Publication.objects.filter(article=1)
<QuerySet [<Publication: The Python Journal>]>
>>> Publication.objects.filter(article=a1)
<QuerySet [<Publication: The Python Journal>]>

>>> Publication.objects.filter(article__in=[1,2]).distinct()
<QuerySet [<Publication: Highlights for Children>, <Publication: Science News>,
↳<Publication: Science Weekly>, <Publication: The Python Journal>]>
>>> Publication.objects.filter(article__in=[a1,a2]).distinct()
<QuerySet [<Publication: Highlights for Children>, <Publication: Science News>,
↳<Publication: Science Weekly>, <Publication: The Python Journal>]>
```

Excluding a related item works as you would expect, too (although the SQL involved is a little complex):

```
>>> Article.objects.exclude(publications=p2)
<QuerySet [<Article: Django lets you build Web apps easily>]>
```

If we delete a *Publication*, its *Articles* won't be able to access it:

```
>>> p1.delete()
>>> Publication.objects.all()
<QuerySet [<Publication: Highlights for Children>, <Publication: Science News>,
↳<Publication: Science Weekly>]>
>>> a1 = Article.objects.get(pk=1)
>>> a1.publications.all()
<QuerySet []>
```

If we delete an *Article*, its *Publications* won't be able to access it:

```
>>> a2.delete()
>>> Article.objects.all()
<QuerySet [<Article: Django lets you build Web apps easily>]>
>>> p2.article_set.all()
<QuerySet []>
```

Adding via the 'other' end of an m2m:

```
>>> a4 = Article(headline='NASA finds intelligent life on Earth')
>>> a4.save()
```

```
>>> p2.article_set.add(a4)
>>> p2.article_set.all()
<QuerySet [<Article: NASA finds intelligent life on Earth>]>
>>> a4.publications.all()
<QuerySet [<Publication: Science News>]>
```

Adding via the other end using keywords:

```
>>> new_article = p2.article_set.create(headline='Oxygen-free diet works wonders')
>>> p2.article_set.all()
<QuerySet [<Article: NASA finds intelligent life on Earth>, <Article: Oxygen-free_
↳diet works wonders>]>
>>> a5 = p2.article_set.all()[1]
>>> a5.publications.all()
<QuerySet [<Publication: Science News>]>
```

Removing Publication from an Article:

```
>>> a4.publications.remove(p2)
>>> p2.article_set.all()
<QuerySet [<Article: Oxygen-free diet works wonders>]>
>>> a4.publications.all()
<QuerySet []>
```

And from the other end:

```
>>> p2.article_set.remove(a5)
>>> p2.article_set.all()
<QuerySet []>
>>> a5.publications.all()
<QuerySet []>
```

Relation sets can be set:

```
>>> a4.publications.all()
<QuerySet [<Publication: Science News>]>
>>> a4.publications.set([p3])
>>> a4.publications.all()
<QuerySet [<Publication: Science Weekly>]>
```

Relation sets can be cleared:

```
>>> p2.article_set.clear()
>>> p2.article_set.all()
<QuerySet []>
```

And you can clear from the other end:

```
>>> p2.article_set.add(a4, a5)
>>> p2.article_set.all()
<QuerySet [<Article: NASA finds intelligent life on Earth>, <Article: Oxygen-free_
↳diet works wonders>]>
>>> a4.publications.all()
<QuerySet [<Publication: Science News>, <Publication: Science Weekly>]>
>>> a4.publications.clear()
>>> a4.publications.all()
<QuerySet []>
```

```
>>> p2.article_set.all()
<QuerySet [<Article: Oxygen-free diet works wonders>]>
```

Recreate the Article and Publication we have deleted:

```
>>> p1 = Publication(title='The Python Journal')
>>> p1.save()
>>> a2 = Article(headline='NASA uses Python')
>>> a2.save()
>>> a2.publications.add(p1, p2, p3)
```

Bulk delete some Publications - references to deleted publications should go:

```
>>> Publication.objects.filter(title__startswith='Science').delete()
>>> Publication.objects.all()
<QuerySet [<Publication: Highlights for Children>, <Publication: The Python Journal>]>
>>> Article.objects.all()
<QuerySet [<Article: Django lets you build Web apps easily>, <Article: NASA finds_
↳intelligent life on Earth>, <Article: NASA uses Python>, <Article: Oxygen-free diet_
↳works wonders>]>
>>> a2.publications.all()
<QuerySet [<Publication: The Python Journal>]>
```

Bulk delete some articles - references to deleted objects should go:

```
>>> q = Article.objects.filter(headline__startswith='Django')
>>> print(q)
<QuerySet [<Article: Django lets you build Web apps easily>]>
>>> q.delete()
```

After the `delete()`, the `QuerySet` cache needs to be cleared, and the referenced objects should be gone:

```
>>> print(q)
<QuerySet []>
>>> p1.article_set.all()
<QuerySet [<Article: NASA uses Python>]>
```

## Many-to-one relationships

To define a many-to-one relationship, use `ForeignKey`:

```
from django.db import models

class Reporter(models.Model):
    first_name = models.CharField(max_length=30)
    last_name = models.CharField(max_length=30)
    email = models.EmailField()

    def __str__(self):
        # __unicode__ on Python 2
        return "%s %s" % (self.first_name, self.last_name)

class Article(models.Model):
    headline = models.CharField(max_length=100)
    pub_date = models.DateField()
    reporter = models.ForeignKey(Reporter, on_delete=models.CASCADE)
```

```
def __str__(self): # __unicode__ on Python 2
    return self.headline

class Meta:
    ordering = ('headline',)
```

What follows are examples of operations that can be performed using the Python API facilities.

Create a few Reporters:

```
>>> r = Reporter(first_name='John', last_name='Smith', email='john@example.com')
>>> r.save()

>>> r2 = Reporter(first_name='Paul', last_name='Jones', email='paul@example.com')
>>> r2.save()
```

Create an Article:

```
>>> from datetime import date
>>> a = Article(id=None, headline="This is a test", pub_date=date(2005, 7, 27),
↳ reporter=r)
>>> a.save()

>>> a.reporter.id
1

>>> a.reporter
<Reporter: John Smith>
```

Note that you must save an object before it can be assigned to a foreign key relationship. For example, creating an Article with unsaved Reporter raises ValueError:

```
>>> r3 = Reporter(first_name='John', last_name='Smith', email='john@example.com')
>>> Article.objects.create(headline="This is a test", pub_date=date(2005, 7, 27),
↳ reporter=r3)
Traceback (most recent call last):
...
ValueError: save() prohibited to prevent data loss due to unsaved related object
↳ 'reporter'.
```

Article objects have access to their related Reporter objects:

```
>>> r = a.reporter
```

On Python 2, these are strings of type `str` instead of unicode strings because that's what was used in the creation of this reporter (and we haven't refreshed the data from the database, which always returns unicode strings):

```
>>> r.first_name, r.last_name
('John', 'Smith')
```

Create an Article via the Reporter object:

```
>>> new_article = r.article_set.create(headline="John's second story", pub_
↳ date=date(2005, 7, 29))
>>> new_article
<Article: John's second story>
>>> new_article.reporter
<Reporter: John Smith>
```

```
>>> new_article.reporter.id
1
```

Create a new article, and add it to the article set:

```
>>> new_article2 = Article(headline="Paul's story", pub_date=date(2006, 1, 17))
>>> r.article_set.add(new_article2)
>>> new_article2.reporter
<Reporter: John Smith>
>>> new_article2.reporter.id
1
>>> r.article_set.all()
<QuerySet [<Article: John's second story>, <Article: Paul's story>, <Article: This is a
↳ test>]>
```

Add the same article to a different article set - check that it moves:

```
>>> r2.article_set.add(new_article2)
>>> new_article2.reporter.id
2
>>> new_article2.reporter
<Reporter: Paul Jones>
```

Adding an object of the wrong type raises TypeError:

```
>>> r.article_set.add(r2)
Traceback (most recent call last):
...
TypeError: 'Article' instance expected

>>> r.article_set.all()
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
>>> r2.article_set.all()
<QuerySet [<Article: Paul's story>]>

>>> r.article_set.count()
2

>>> r2.article_set.count()
1
```

Note that in the last example the article has moved from John to Paul.

Related managers support field lookups as well. The API automatically follows relationships as far as you need. Use double underscores to separate relationships. This works as many levels deep as you want. There's no limit. For example:

```
>>> r.article_set.filter(headline__startswith='This')
<QuerySet [<Article: This is a test>]>

# Find all Articles for any Reporter whose first name is "John".
>>> Article.objects.filter(reporter__first_name='John')
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
```

Exact match is implied here:

```
>>> Article.objects.filter(reporter__first_name='John')
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
```

Query twice over the related field. This translates to an AND condition in the WHERE clause:

```
>>> Article.objects.filter(reporter__first_name='John', reporter__last_name='Smith')
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
```

For the related lookup you can supply a primary key value or pass the related object explicitly:

```
>>> Article.objects.filter(reporter__pk=1)
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
>>> Article.objects.filter(reporter=1)
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
>>> Article.objects.filter(reporter=r)
<QuerySet [<Article: John's second story>, <Article: This is a test>]>

>>> Article.objects.filter(reporter__in=[1,2]).distinct()
<QuerySet [<Article: John's second story>, <Article: Paul's story>, <Article: This is a
↳a test>]>
>>> Article.objects.filter(reporter__in=[r,r2]).distinct()
<QuerySet [<Article: John's second story>, <Article: Paul's story>, <Article: This is a
↳a test>]>
```

You can also use a queryset instead of a literal list of instances:

```
>>> Article.objects.filter(reporter__in=Reporter.objects.filter(first_name='John')).
↳distinct()
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
```

Querying in the opposite direction:

```
>>> Reporter.objects.filter(article__pk=1)
<QuerySet [<Reporter: John Smith>]>
>>> Reporter.objects.filter(article=1)
<QuerySet [<Reporter: John Smith>]>
>>> Reporter.objects.filter(article=a)
<QuerySet [<Reporter: John Smith>]>

>>> Reporter.objects.filter(article__headline__startswith='This')
<QuerySet [<Reporter: John Smith>, <Reporter: John Smith>, <Reporter: John Smith>]>
>>> Reporter.objects.filter(article__headline__startswith='This').distinct()
<QuerySet [<Reporter: John Smith>]>
```

Counting in the opposite direction works in conjunction with distinct():

```
>>> Reporter.objects.filter(article__headline__startswith='This').count()
3
>>> Reporter.objects.filter(article__headline__startswith='This').distinct().count()
1
```

Queries can go round in circles:

```
>>> Reporter.objects.filter(article__reporter__first_name__startswith='John')
<QuerySet [<Reporter: John Smith>, <Reporter: John Smith>, <Reporter: John Smith>,
↳<Reporter: John Smith>]>
>>> Reporter.objects.filter(article__reporter__first_name__startswith='John').
↳distinct()
<QuerySet [<Reporter: John Smith>]>
>>> Reporter.objects.filter(article__reporter=r).distinct()
<QuerySet [<Reporter: John Smith>]>
```

If you delete a reporter, his articles will be deleted (assuming that the ForeignKey was defined with `django.db.models.ForeignKey.on_delete` set to `CASCADE`, which is the default):

```
>>> Article.objects.all()
<QuerySet [<Article: John's second story>, <Article: Paul's story>, <Article: This is a
↳a test>]>
>>> Reporter.objects.order_by('first_name')
<QuerySet [<Reporter: John Smith>, <Reporter: Paul Jones>]>
>>> r2.delete()
>>> Article.objects.all()
<QuerySet [<Article: John's second story>, <Article: This is a test>]>
>>> Reporter.objects.order_by('first_name')
<QuerySet [<Reporter: John Smith>]>
```

You can delete using a JOIN in the query:

```
>>> Reporter.objects.filter(article__headline__startswith='This').delete()
>>> Reporter.objects.all()
<QuerySet []>
>>> Article.objects.all()
<QuerySet []>
```

## One-to-one relationships

To define a one-to-one relationship, use `OneToOneField`.

In this example, a `Place` optionally can be a `Restaurant`:

```
from django.db import models

class Place(models.Model):
    name = models.CharField(max_length=50)
    address = models.CharField(max_length=80)

    def __str__(self):
        # __unicode__ on Python 2
        return "%s the place" % self.name

class Restaurant(models.Model):
    place = models.OneToOneField(
        Place,
        on_delete=models.CASCADE,
        primary_key=True,
    )
    serves_hot_dogs = models.BooleanField(default=False)
    serves_pizza = models.BooleanField(default=False)

    def __str__(self):
        # __unicode__ on Python 2
        return "%s the restaurant" % self.place.name

class Waiter(models.Model):
    restaurant = models.ForeignKey(Restaurant, on_delete=models.CASCADE)
    name = models.CharField(max_length=50)

    def __str__(self):
        # __unicode__ on Python 2
        return "%s the waiter at %s" % (self.name, self.restaurant)
```

What follows are examples of operations that can be performed using the Python API facilities.

Create a couple of Places:

```
>>> p1 = Place(name='Demon Dogs', address='944 W. Fullerton')
>>> p1.save()
>>> p2 = Place(name='Ace Hardware', address='1013 N. Ashland')
>>> p2.save()
```

Create a Restaurant. Pass the ID of the “parent” object as this object’s ID:

```
>>> r = Restaurant(place=p1, serves_hot_dogs=True, serves_pizza=False)
>>> r.save()
```

A Restaurant can access its place:

```
>>> r.place
<Place: Demon Dogs the place>
```

A Place can access its restaurant, if available:

```
>>> p1.restaurant
<Restaurant: Demon Dogs the restaurant>
```

p2 doesn’t have an associated restaurant:

```
>>> from django.core.exceptions import ObjectDoesNotExist
>>> try:
>>>     p2.restaurant
>>> except ObjectDoesNotExist:
>>>     print("There is no restaurant here.")
There is no restaurant here.
```

You can also use `hasattr` to avoid the need for exception catching:

```
>>> hasattr(p2, 'restaurant')
False
```

Set the place using assignment notation. Because `place` is the primary key on `Restaurant`, the save will create a new restaurant:

```
>>> r.place = p2
>>> r.save()
>>> p2.restaurant
<Restaurant: Ace Hardware the restaurant>
>>> r.place
<Place: Ace Hardware the place>
```

Set the place back again, using assignment in the reverse direction:

```
>>> p1.restaurant = r
>>> p1.restaurant
<Restaurant: Demon Dogs the restaurant>
```

Note that you must save an object before it can be assigned to a one-to-one relationship. For example, creating a `Restaurant` with unsaved `Place` raises `ValueError`:

```
>>> p3 = Place(name='Demon Dogs', address='944 W. Fullerton')
>>> Restaurant.objects.create(place=p3, serves_hot_dogs=True, serves_pizza=False)
Traceback (most recent call last):
```

```
...
ValueError: save() prohibited to prevent data loss due to unsaved related object
↳ 'place'.
```

`Restaurant.objects.all()` just returns the Restaurants, not the Places. Note that there are two restaurants - Ace Hardware the Restaurant was created in the call to `r.place = p2`:

```
>>> Restaurant.objects.all()
<QuerySet [<Restaurant: Demon Dogs the restaurant>, <Restaurant: Ace Hardware the_
↳ restaurant>]>
```

`Place.objects.all()` returns all Places, regardless of whether they have Restaurants:

```
>>> Place.objects.order_by('name')
<QuerySet [<Place: Ace Hardware the place>, <Place: Demon Dogs the place>]>
```

You can query the models using *lookups across relationships*:

```
>>> Restaurant.objects.get(place=p1)
<Restaurant: Demon Dogs the restaurant>
>>> Restaurant.objects.get(place__pk=1)
<Restaurant: Demon Dogs the restaurant>
>>> Restaurant.objects.filter(place__name__startswith="Demon")
<QuerySet [<Restaurant: Demon Dogs the restaurant>]>
>>> Restaurant.objects.exclude(place__address__contains="Ashland")
<QuerySet [<Restaurant: Demon Dogs the restaurant>]>
```

This of course works in reverse:

```
>>> Place.objects.get(pk=1)
<Place: Demon Dogs the place>
>>> Place.objects.get(restaurant__place=p1)
<Place: Demon Dogs the place>
>>> Place.objects.get(restaurant=r)
<Place: Demon Dogs the place>
>>> Place.objects.get(restaurant__place__name__startswith="Demon")
<Place: Demon Dogs the place>
```

Add a Waiter to the Restaurant:

```
>>> w = r.waiter_set.create(name='Joe')
>>> w
<Waiter: Joe the waiter at Demon Dogs the restaurant>
```

Query the waiters:

```
>>> Waiter.objects.filter(restaurant__place=p1)
<QuerySet [<Waiter: Joe the waiter at Demon Dogs the restaurant>]>
>>> Waiter.objects.filter(restaurant__place__name__startswith="Demon")
<QuerySet [<Waiter: Joe the waiter at Demon Dogs the restaurant>]>
```

## 3.3 Handling HTTP requests

Information on handling HTTP requests in Django:

### 3.3.1 URL dispatcher

A clean, elegant URL scheme is an important detail in a high-quality Web application. Django lets you design URLs however you want, with no framework limitations.

There's no `.php` or `.cgi` required, and certainly none of that `0,2097,1-1-1928,00` nonsense.

See [Cool URIs don't change](#), by World Wide Web creator Tim Berners-Lee, for excellent arguments on why URLs should be clean and usable.

#### Overview

To design URLs for an app, you create a Python module informally called a **URLconf** (URL configuration). This module is pure Python code and is a simple mapping between URL patterns (simple regular expressions) to Python functions (your views).

This mapping can be as short or as long as needed. It can reference other mappings. And, because it's pure Python code, it can be constructed dynamically.

Django also provides a way to translate URLs according to the active language. See the [internationalization documentation](#) for more information.

#### How Django processes a request

When a user requests a page from your Django-powered site, this is the algorithm the system follows to determine which Python code to execute:

1. Django determines the root URLconf module to use. Ordinarily, this is the value of the `ROOT_URLCONF` setting, but if the incoming `HttpRequest` object has a `urlconf` attribute (set by middleware), its value will be used in place of the `ROOT_URLCONF` setting.
2. Django loads that Python module and looks for the variable `urlpatterns`. This should be a Python list of `django.conf.urls.url()` instances.
3. Django runs through each URL pattern, in order, and stops at the first one that matches the requested URL.
4. Once one of the regexes matches, Django imports and calls the given view, which is a simple Python function (or a *class-based view*). The view gets passed the following arguments:
  - An instance of `HttpRequest`.
  - If the matched regular expression returned no named groups, then the matches from the regular expression are provided as positional arguments.
  - The keyword arguments are made up of any named groups matched by the regular expression, overridden by any arguments specified in the optional `kwargs` argument to `django.conf.urls.url()`.
5. If no regex matches, or if an exception is raised during any point in this process, Django invokes an appropriate error-handling view. See [Error handling](#) below.

#### Example

Here's a sample URLconf:

```
from django.conf.urls import url

from . import views
```

```
urlpatterns = [
    url(r'^articles/2003/$', views.special_case_2003),
    url(r'^articles/([0-9]{4})/$', views.year_archive),
    url(r'^articles/([0-9]{4})/([0-9]{2})/$', views.month_archive),
    url(r'^articles/([0-9]{4})/([0-9]{2})/([0-9]+)/$', views.article_detail),
]
```

**Notes:**

- To capture a value from the URL, just put parenthesis around it.
- There's no need to add a leading slash, because every URL has that. For example, it's `^articles`, not `^/articles`.
- The `'r'` in front of each regular expression string is optional but recommended. It tells Python that a string is “raw” – that nothing in the string should be escaped. See [Dive Into Python's explanation](#).

**Example requests:**

- A request to `/articles/2005/03/` would match the third entry in the list. Django would call the function `views.month_archive(request, '2005', '03')`.
- `/articles/2005/3/` would not match any URL patterns, because the third entry in the list requires two digits for the month.
- `/articles/2003/` would match the first pattern in the list, not the second one, because the patterns are tested in order, and the first one is the first test to pass. Feel free to exploit the ordering to insert special cases like this. Here, Django would call the function `views.special_case_2003(request)`
- `/articles/2003` would not match any of these patterns, because each pattern requires that the URL end with a slash.
- `/articles/2003/03/03/` would match the final pattern. Django would call the function `views.article_detail(request, '2003', '03', '03')`.

**Named groups**

The above example used simple, *non-named* regular-expression groups (via parenthesis) to capture bits of the URL and pass them as *positional* arguments to a view. In more advanced usage, it's possible to use *named* regular-expression groups to capture URL bits and pass them as *keyword* arguments to a view.

In Python regular expressions, the syntax for named regular-expression groups is `(?P<name>pattern)`, where `name` is the name of the group and `pattern` is some pattern to match.

Here's the above example URLconf, rewritten to use named groups:

```
from django.conf.urls import url

from . import views

urlpatterns = [
    url(r'^articles/2003/$', views.special_case_2003),
    url(r'^articles/(?P<year>[0-9]{4})/$', views.year_archive),
    url(r'^articles/(?P<year>[0-9]{4})/(?P<month>[0-9]{2})/$', views.month_archive),
    url(r'^articles/(?P<year>[0-9]{4})/(?P<month>[0-9]{2})/(?P<day>[0-9]{2})/$',
↪views.article_detail),
]
```

This accomplishes exactly the same thing as the previous example, with one subtle difference: The captured values are passed to view functions as keyword arguments rather than positional arguments. For example:

- A request to `/articles/2005/03/` would call the function `views.month_archive(request, year='2005', month='03')`, instead of `views.month_archive(request, '2005', '03')`.
- A request to `/articles/2003/03/03/` would call the function `views.article_detail(request, year='2003', month='03', day='03')`.

In practice, this means your URLconfs are slightly more explicit and less prone to argument-order bugs – and you can reorder the arguments in your views’ function definitions. Of course, these benefits come at the cost of brevity; some developers find the named-group syntax ugly and too verbose.

## The matching/grouping algorithm

Here’s the algorithm the URLconf parser follows, with respect to named groups vs. non-named groups in a regular expression:

1. If there are any named arguments, it will use those, ignoring non-named arguments.
2. Otherwise, it will pass all non-named arguments as positional arguments.

In both cases, any extra keyword arguments that have been given as per *Passing extra options to view functions* (below) will also be passed to the view.

## What the URLconf searches against

The URLconf searches against the requested URL, as a normal Python string. This does not include GET or POST parameters, or the domain name.

For example, in a request to `https://www.example.com/myapp/`, the URLconf will look for `myapp/`.

In a request to `https://www.example.com/myapp/?page=3`, the URLconf will look for `myapp/`.

The URLconf doesn’t look at the request method. In other words, all request methods – POST, GET, HEAD, etc. – will be routed to the same function for the same URL.

## Captured arguments are always strings

Each captured argument is sent to the view as a plain Python string, regardless of what sort of match the regular expression makes. For example, in this URLconf line:

```
url(r'^articles/(?P<year>[0-9]{4})/$', views.year_archive),
```

...the `year` argument passed to `views.year_archive()` will be a string, not an integer, even though the `[0-9]{4}` will only match integer strings.

## Specifying defaults for view arguments

A convenient trick is to specify default parameters for your views’ arguments. Here’s an example URLconf and view:

```
# URLconf
from django.conf.urls import url

from . import views

urlpatterns = [
    url(r'^blog/$', views.page),
    url(r'^blog/page(?P<num>[0-9]+)/$', views.page),
```

```

]

# View (in blog/views.py)
def page(request, num="1"):
    # Output the appropriate page of blog entries, according to num.
    ...

```

In the above example, both URL patterns point to the same view – `views.page` – but the first pattern doesn’t capture anything from the URL. If the first pattern matches, the `page()` function will use its default argument for `num`, `"1"`. If the second pattern matches, `page()` will use whatever `num` value was captured by the regex.

## Performance

Each regular expression in a `urlpatterns` is compiled the first time it’s accessed. This makes the system blazingly fast.

## Syntax of the `urlpatterns` variable

`urlpatterns` should be a Python list of `url()` instances.

## Error handling

When Django can’t find a regex matching the requested URL, or when an exception is raised, Django will invoke an error-handling view.

The views to use for these cases are specified by four variables. Their default values should suffice for most projects, but further customization is possible by overriding their default values.

See the documentation on [customizing error views](#) for the full details.

Such values can be set in your root `URLconf`. Setting these variables in any other `URLconf` will have no effect.

Values must be callables, or strings representing the full Python import path to the view that should be called to handle the error condition at hand.

The variables are:

- `handler400` – See `django.conf.urls.handler400`.
- `handler403` – See `django.conf.urls.handler403`.
- `handler404` – See `django.conf.urls.handler404`.
- `handler500` – See `django.conf.urls.handler500`.

## Including other `URLconfs`

At any point, your `urlpatterns` can “include” other `URLconf` modules. This essentially “roots” a set of URLs below other ones.

For example, here’s an excerpt of the `URLconf` for the Django website itself. It includes a number of other `URLconfs`:

```

from django.conf.urls import include, url

urlpatterns = [
    # ... snip ...

```

```
url(r'^community/', include('django_website.aggregator.urls')),
url(r'^contact/', include('django_website.contact.urls')),
# ... snip ...
]
```

Note that the regular expressions in this example don't have a `$` (end-of-string match character) but do include a trailing slash. Whenever Django encounters `include()` (`django.conf.urls.include()`), it chops off whatever part of the URL matched up to that point and sends the remaining string to the included URLconf for further processing.

Another possibility is to include additional URL patterns by using a list of `url()` instances. For example, consider this URLconf:

```
from django.conf.urls import include, url

from apps.main import views as main_views
from credit import views as credit_views

extra_patterns = [
    url(r'^reports/$', credit_views.report),
    url(r'^reports/(?P<id>[0-9]+)/$', credit_views.report),
    url(r'^charge/$', credit_views.charge),
]

urlpatterns = [
    url(r'^$', main_views.homepage),
    url(r'^help/', include('apps.help.urls')),
    url(r'^credit/', include(extra_patterns)),
]
```

In this example, the `/credit/reports/` URL will be handled by the `credit_views.report()` Django view.

This can be used to remove redundancy from URLconfs where a single pattern prefix is used repeatedly. For example, consider this URLconf:

```
from django.conf.urls import url
from . import views

urlpatterns = [
    url(r'^(?P<page_slug>[\w-]+)-(?P<page_id>\w+)/history/$', views.history),
    url(r'^(?P<page_slug>[\w-]+)-(?P<page_id>\w+)/edit/$', views.edit),
    url(r'^(?P<page_slug>[\w-]+)-(?P<page_id>\w+)/discuss/$', views.discuss),
    url(r'^(?P<page_slug>[\w-]+)-(?P<page_id>\w+)/permissions/$', views.permissions),
]
```

We can improve this by stating the common path prefix only once and grouping the suffixes that differ:

```
from django.conf.urls import include, url
from . import views

urlpatterns = [
    url(r'^(?P<page_slug>[\w-]+)-(?P<page_id>\w+)/', include([
        url(r'^history/$', views.history),
        url(r'^edit/$', views.edit),
        url(r'^discuss/$', views.discuss),
        url(r'^permissions/$', views.permissions),
    ])),
]
```

## Captured parameters

An included URLconf receives any captured parameters from parent URLconfs, so the following example is valid:

```
# In settings/urls/main.py
from django.conf.urls import include, url

urlpatterns = [
    url(r'^(?P<username>\w+)/blog/', include('foo.urls.blog')),
]

# In foo/urls/blog.py
from django.conf.urls import url
from . import views

urlpatterns = [
    url(r'^$', views.blog.index),
    url(r'^archive/$', views.blog.archive),
]
```

In the above example, the captured "username" variable is passed to the included URLconf, as expected.

## Nested arguments

Regular expressions allow nested arguments, and Django will resolve them and pass them to the view. When reversing, Django will try to fill in all outer captured arguments, ignoring any nested captured arguments. Consider the following URL patterns which optionally take a page argument:

```
from django.conf.urls import url

urlpatterns = [
    url(r'blog/(page-(\d+)/)?$', blog_articles), # bad
    url(r'comments/(? :page-(?P<page_number>\d+)/)?$', comments), # good
]
```

Both patterns use nested arguments and will resolve: for example, `blog/page-2/` will result in a match to `blog_articles` with two positional arguments: `page-2/` and `2`. The second pattern for `comments` will match `comments/page-2/` with keyword argument `page_number` set to `2`. The outer argument in this case is a non-capturing argument (`?:...`).

The `blog_articles` view needs the outermost captured argument to be reversed, `page-2/` or no arguments in this case, while `comments` can be reversed with either no arguments or a value for `page_number`.

Nested captured arguments create a strong coupling between the view arguments and the URL as illustrated by `blog_articles`: the view receives part of the URL (`page-2/`) instead of only the value the view is interested in. This coupling is even more pronounced when reversing, since to reverse the view we need to pass the piece of URL instead of the page number.

As a rule of thumb, only capture the values the view needs to work with and use non-capturing arguments when the regular expression needs an argument but the view ignores it.

## Passing extra options to view functions

URLconfs have a hook that lets you pass extra arguments to your view functions, as a Python dictionary.

The `django.conf.urls.url()` function can take an optional third argument which should be a dictionary of extra keyword arguments to pass to the view function.

For example:

```
from django.conf.urls import url
from . import views

urlpatterns = [
    url(r'^blog/(?P<year>[0-9]{4})/$', views.year_archive, {'foo': 'bar'}),
]
```

In this example, for a request to `/blog/2005/`, Django will call `views.year_archive(request, year='2005', foo='bar')`.

This technique is used in the *syndication framework* to pass metadata and options to views.

---

### Dealing with conflicts

It's possible to have a URL pattern which captures named keyword arguments, and also passes arguments with the same names in its dictionary of extra arguments. When this happens, the arguments in the dictionary will be used instead of the arguments captured in the URL.

---

### Passing extra options to `include()`

Similarly, you can pass extra options to `include()`. When you pass extra options to `include()`, *each* line in the included URLconf will be passed the extra options.

For example, these two URLconf sets are functionally identical:

Set one:

```
# main.py
from django.conf.urls import include, url

urlpatterns = [
    url(r'^blog/', include('inner'), {'blogid': 3}),
]

# inner.py
from django.conf.urls import url
from mysite import views

urlpatterns = [
    url(r'^archive/$', views.archive),
    url(r'^about/$', views.about),
]
```

Set two:

```
# main.py
from django.conf.urls import include, url
from mysite import views

urlpatterns = [
    url(r'^blog/', include('inner')),
]

# inner.py
```

```

from django.conf.urls import url

urlpatterns = [
    url(r'^archive/$', views.archive, {'blogid': 3}),
    url(r'^about/$', views.about, {'blogid': 3}),
]

```

Note that extra options will *always* be passed to *every* line in the included URLconf, regardless of whether the line's view actually accepts those options as valid. For this reason, this technique is only useful if you're certain that every view in the included URLconf accepts the extra options you're passing.

## Reverse resolution of URLs

A common need when working on a Django project is the possibility to obtain URLs in their final forms either for embedding in generated content (views and assets URLs, URLs shown to the user, etc.) or for handling of the navigation flow on the server side (redirections, etc.)

It is strongly desirable to avoid hard-coding these URLs (a laborious, non-scalable and error-prone strategy). Equally dangerous is devising ad-hoc mechanisms to generate URLs that are parallel to the design described by the URLconf, which can result in the production of URLs that become stale over time.

In other words, what's needed is a DRY mechanism. Among other advantages it would allow evolution of the URL design without having to go over all the project source code to search and replace outdated URLs.

The primary piece of information we have available to get a URL is an identification (e.g. the name) of the view in charge of handling it. Other pieces of information that necessarily must participate in the lookup of the right URL are the types (positional, keyword) and values of the view arguments.

Django provides a solution such that the URL mapper is the only repository of the URL design. You feed it with your URLconf and then it can be used in both directions:

- Starting with a URL requested by the user/browser, it calls the right Django view providing any arguments it might need with their values as extracted from the URL.
- Starting with the identification of the corresponding Django view plus the values of arguments that would be passed to it, obtain the associated URL.

The first one is the usage we've been discussing in the previous sections. The second one is what is known as *reverse resolution of URLs*, *reverse URL matching*, *reverse URL lookup*, or simply *URL reversing*.

Django provides tools for performing URL reversing that match the different layers where URLs are needed:

- In templates: Using the `url` template tag.
- In Python code: Using the `reverse()` function.
- In higher level code related to handling of URLs of Django model instances: The `get_absolute_url()` method.

## Examples

Consider again this URLconf entry:

```

from django.conf.urls import url

from . import views

urlpatterns = [

```

```
#...
url(r'^articles/([0-9]{4})/$', views.year_archive, name='news-year-archive'),
#...
]
```

According to this design, the URL for the archive corresponding to year *nnnn* is `/articles/nnnn/`.

You can obtain these in template code by using:

```
<a href="{% url 'news-year-archive' 2012 %}">2012 Archive</a>
{# Or with the year in a template context variable: #}
<ul>
{% for yearvar in year_list %}
<li><a href="{% url 'news-year-archive' yearvar %}">{{ yearvar }} Archive</a></li>
{% endfor %}
</ul>
```

Or in Python code:

```
from django.urls import reverse
from django.http import HttpResponseRedirect

def redirect_to_year(request):
    # ...
    year = 2006
    # ...
    return HttpResponseRedirect(reverse('news-year-archive', args=(year,)))
```

If, for some reason, it was decided that the URLs where content for yearly article archives are published at should be changed then you would only need to change the entry in the URLconf.

In some scenarios where views are of a generic nature, a many-to-one relationship might exist between URLs and views. For these cases the view name isn't a good enough identifier for it when comes the time of reversing URLs. Read the next section to know about the solution Django provides for this.

## Naming URL patterns

In order to perform URL reversing, you'll need to use **named URL patterns** as done in the examples above. The string used for the URL name can contain any characters you like. You are not restricted to valid Python names.

When you name your URL patterns, make sure you use names that are unlikely to clash with any other application's choice of names. If you call your URL pattern `comment`, and another application does the same thing, there's no guarantee which URL will be inserted into your template when you use this name.

Putting a prefix on your URL names, perhaps derived from the application name, will decrease the chances of collision. We recommend something like `myapp-comment` instead of `comment`.

## URL namespaces

### Introduction

URL namespaces allow you to uniquely reverse *named URL patterns* even if different applications use the same URL names. It's a good practice for third-party apps to always use namespaced URLs (as we did in the tutorial). Similarly, it also allows you to reverse URLs if multiple instances of an application are deployed. In other words, since multiple instances of a single application will share named URLs, namespaces provide a way to tell these named URLs apart.

Django applications that make proper use of URL namespacing can be deployed more than once for a particular site. For example `django.contrib.admin` has an `AdminSite` class which allows you to easily *deploy more than one instance of the admin*. In a later example, we'll discuss the idea of deploying the polls application from the tutorial in two different locations so we can serve the same functionality to two different audiences (authors and publishers).

A URL namespace comes in two parts, both of which are strings:

**application namespace** This describes the name of the application that is being deployed. Every instance of a single application will have the same application namespace. For example, Django's admin application has the somewhat predictable application namespace of `'admin'`.

**instance namespace** This identifies a specific instance of an application. Instance namespaces should be unique across your entire project. However, an instance namespace can be the same as the application namespace. This is used to specify a default instance of an application. For example, the default Django admin instance has an instance namespace of `'admin'`.

Namespaced URLs are specified using the `' : '` operator. For example, the main index page of the admin application is referenced using `'admin:index'`. This indicates a namespace of `'admin'`, and a named URL of `'index'`.

Namespaces can also be nested. The named URL `'sports:polls:index'` would look for a pattern named `'index'` in the namespace `'polls'` that is itself defined within the top-level namespace `'sports'`.

## Reversing namespaced URLs

When given a namespaced URL (e.g. `'polls:index'`) to resolve, Django splits the fully qualified name into parts and then tries the following lookup:

1. First, Django looks for a matching *application namespace* (in this example, `'polls'`). This will yield a list of instances of that application.
2. If there is a current application defined, Django finds and returns the URL resolver for that instance. The current application can be specified with the `current_app` argument to the `reverse()` function.

The `url` template tag uses the namespace of the currently resolved view as the current application in a `RequestContext`. You can override this default by setting the current application on the `request.current_app` attribute.

Previously, the `url` template tag did not use the namespace of the currently resolved view and you had to set the `current_app` attribute on the request.

3. If there is no current application. Django looks for a default application instance. The default application instance is the instance that has an *instance namespace* matching the *application namespace* (in this example, an instance of `polls` called `'polls'`).
4. If there is no default application instance, Django will pick the last deployed instance of the application, whatever its instance name may be.
5. If the provided namespace doesn't match an *application namespace* in step 1, Django will attempt a direct lookup of the namespace as an *instance namespace*.

If there are nested namespaces, these steps are repeated for each part of the namespace until only the view name is unresolved. The view name will then be resolved into a URL in the namespace that has been found.

## Example

To show this resolution strategy in action, consider an example of two instances of the `polls` application from the tutorial: one called `'author-polls'` and one called `'publisher-polls'`. Assume we have enhanced that application so that it takes the instance namespace into consideration when creating and displaying polls.

```
urls.py

from django.conf.urls import include, url

urlpatterns = [
    url(r'^author-polls/', include('polls.urls', namespace='author-polls')),
    url(r'^publisher-polls/', include('polls.urls', namespace='publisher-polls')),
]
```

```
polls/urls.py

from django.conf.urls import url

from . import views

app_name = 'polls'
urlpatterns = [
    url(r'^$', views.IndexView.as_view(), name='index'),
    url(r'^(?P<pk>\d+)/$', views.DetailView.as_view(), name='detail'),
    ...
]
```

Using this setup, the following lookups are possible:

- If one of the instances is current - say, if we were rendering the detail page in the instance 'author-polls' - 'polls:index' will resolve to the index page of the 'author-polls' instance; i.e. both of the following will result in "/author-polls/".

In the method of a class-based view:

```
reverse('polls:index', current_app=self.request.resolver_match.namespace)
```

and in the template:

```
{% url 'polls:index' %}
```

- If there is no current instance - say, if we were rendering a page somewhere else on the site - 'polls:index' will resolve to the last registered instance of `polls`. Since there is no default instance (instance namespace of 'polls'), the last instance of `polls` that is registered will be used. This would be 'publisher-polls' since it's declared last in the `urlpatterns`.
- 'author-polls:index' will always resolve to the index page of the instance 'author-polls' (and likewise for 'publisher-polls').

If there were also a default instance - i.e., an instance named 'polls' - the only change from above would be in the case where there is no current instance (the second item in the list above). In this case 'polls:index' would resolve to the index page of the default instance instead of the instance declared last in `urlpatterns`.

## URL namespaces and included URLconfs

Application namespaces of included URLconfs can be specified in two ways.

Firstly, you can set an `app_name` attribute in the included URLconf module, at the same level as the `urlpatterns` attribute. You have to pass the actual module, or a string reference to the module, to `include()`, not the list of `urlpatterns` itself.

```
polls/urls.py

from django.conf.urls import url

from . import views
```

```
app_name = 'polls'
urlpatterns = [
    url(r'^$', views.IndexView.as_view(), name='index'),
    url(r'^(?P<pk>\d+)/$', views.DetailView.as_view(), name='detail'),
    ...
]
```

urls.py

```
from django.conf.urls import include, url

urlpatterns = [
    url(r'^polls/', include('polls.urls')),
]
```

The URLs defined in `polls.urls` will have an application namespace `polls`.

Secondly, you can include an object that contains embedded namespace data. If you `include()` a list of `url()` instances, the URLs contained in that object will be added to the global namespace. However, you can also `include()` a 2-tuple containing:

```
(<list of url() instances>, <application namespace>)
```

For example:

```
from django.conf.urls import include, url

from . import views

polls_patterns = ([
    url(r'^$', views.IndexView.as_view(), name='index'),
    url(r'^(?P<pk>\d+)/$', views.DetailView.as_view(), name='detail'),
], 'polls')

urlpatterns = [
    url(r'^polls/', include(polls_patterns)),
]
```

This will include the nominated URL patterns into the given application namespace.

The instance namespace can be specified using the `namespace` argument to `include()`. If the instance namespace is not specified, it will default to the included URLconf’s application namespace. This means it will also be the default instance for that namespace.

In previous versions, you had to specify both the application namespace and the instance namespace in a single place, either by passing them as parameters to `include()` or by including a 3-tuple containing `(<list of url() instances>, <application namespace>, <instance namespace>)`.

### 3.3.2 Writing views

A view function, or *view* for short, is simply a Python function that takes a Web request and returns a Web response. This response can be the HTML contents of a Web page, or a redirect, or a 404 error, or an XML document, or an image . . . or anything, really. The view itself contains whatever arbitrary logic is necessary to return that response. This code can live anywhere you want, as long as it’s on your Python path. There’s no other requirement—no “magic,” so to speak. For the sake of putting the code *somewhere*, the convention is to put views in a file called `views.py`, placed in your project or application directory.

## A simple view

Here's a view that returns the current date and time, as an HTML document:

```
from django.http import HttpResponse
import datetime

def current_datetime(request):
    now = datetime.datetime.now()
    html = "<html><body>It is now %s.</body></html>" % now
    return HttpResponse(html)
```

Let's step through this code one line at a time:

- First, we import the class `HttpResponse` from the `django.http` module, along with Python's `datetime` library.
- Next, we define a function called `current_datetime`. This is the view function. Each view function takes an `HttpRequest` object as its first parameter, which is typically named `request`.  
Note that the name of the view function doesn't matter; it doesn't have to be named in a certain way in order for Django to recognize it. We're calling it `current_datetime` here, because that name clearly indicates what it does.
- The view returns an `HttpResponse` object that contains the generated response. Each view function is responsible for returning an `HttpResponse` object. (There are exceptions, but we'll get to those later.)

---

## Django's Time Zone

Django includes a `TIME_ZONE` setting that defaults to `America/Chicago`. This probably isn't where you live, so you might want to change it in your settings file.

---

## Mapping URLs to views

So, to recap, this view function returns an HTML page that includes the current date and time. To display this view at a particular URL, you'll need to create a `URLconf`; see [URL dispatcher](#) for instructions.

## Returning errors

Returning HTTP error codes in Django is easy. There are subclasses of `HttpResponse` for a number of common HTTP status codes other than 200 (which means "OK"). You can find the full list of available subclasses in the [request/response](#) documentation. Just return an instance of one of those subclasses instead of a normal `HttpResponse` in order to signify an error. For example:

```
from django.http import HttpResponse, HttpResponseNotFound

def my_view(request):
    # ...
    if foo:
        return HttpResponseNotFound('<h1>Page not found</h1>')
    else:
        return HttpResponse('<h1>Page was found</h1>')
```

There isn't a specialized subclass for every possible HTTP response code, since many of them aren't going to be that common. However, as documented in the [HttpResponse](#) documentation, you can also pass the HTTP status code into the constructor for [HttpResponse](#) to create a return class for any status code you like. For example:

```
from django.http import HttpResponse

def my_view(request):
    # ...

    # Return a "created" (201) response code.
    return HttpResponse(status=201)
```

Because 404 errors are by far the most common HTTP error, there's an easier way to handle those errors.

### The `Http404` exception

```
class django.http.Http404
```

When you return an error such as [HttpResponseNotFound](#), you're responsible for defining the HTML of the resulting error page:

```
return HttpResponseNotFound('<h1>Page not found</h1>')
```

For convenience, and because it's a good idea to have a consistent 404 error page across your site, Django provides an `Http404` exception. If you raise `Http404` at any point in a view function, Django will catch it and return the standard error page for your application, along with an HTTP error code 404.

Example usage:

```
from django.http import Http404
from django.shortcuts import render
from polls.models import Poll

def detail(request, poll_id):
    try:
        p = Poll.objects.get(pk=poll_id)
    except Poll.DoesNotExist:
        raise Http404("Poll does not exist")
    return render(request, 'polls/detail.html', {'poll': p})
```

In order to show customized HTML when Django returns a 404, you can create an HTML template named `404.html` and place it in the top level of your template tree. This template will then be served when `DEBUG` is set to `False`.

When `DEBUG` is `True`, you can provide a message to `Http404` and it will appear in the standard 404 debug template. Use these messages for debugging purposes; they generally aren't suitable for use in a production 404 template.

### Customizing error views

The default error views in Django should suffice for most Web applications, but can easily be overridden if you need any custom behavior. Simply specify the handlers as seen below in your URLconf (setting them anywhere else will have no effect).

The `page_not_found()` view is overridden by `handler404`:

```
handler404 = 'mysite.views.my_custom_page_not_found_view'
```

The `server_error()` view is overridden by `handler500`:

```
handler500 = 'mysite.views.my_custom_error_view'
```

The `permission_denied()` view is overridden by `handler403`:

```
handler403 = 'mysite.views.my_custom_permission_denied_view'
```

The `bad_request()` view is overridden by `handler400`:

```
handler400 = 'mysite.views.my_custom_bad_request_view'
```

#### See also:

Use the `CSRF_FAILURE_VIEW` setting to override the CSRF error view.

### 3.3.3 View decorators

Django provides several decorators that can be applied to views to support various HTTP features.

#### Allowed HTTP methods

The decorators in `django.views.decorators.http` can be used to restrict access to views based on the request method. These decorators will return a `django.http.HttpResponseNotAllowed` if the conditions are not met.

#### `require_http_methods(request_method_list)`

Decorator to require that a view only accepts particular request methods. Usage:

```
from django.views.decorators.http import require_http_methods

@require_http_methods(["GET", "POST"])
def my_view(request):
    # I can assume now that only GET or POST requests make it this far
    # ...
    pass
```

Note that request methods should be in uppercase.

#### `require_GET()`

Decorator to require that a view only accepts the GET method.

#### `require_POST()`

Decorator to require that a view only accepts the POST method.

#### `require_safe()`

Decorator to require that a view only accepts the GET and HEAD methods. These methods are commonly considered “safe” because they should not have the significance of taking an action other than retrieving the requested resource.

---

**Note:** Web servers should automatically strip the content of responses to HEAD requests while leaving the headers unchanged, so you may handle HEAD requests exactly like GET requests in your views. Since some software, such as link checkers, rely on HEAD requests, you might prefer using `require_safe` instead of `require_GET`.

---

## Conditional view processing

The following decorators in `django.views.decorators.http` can be used to control caching behavior on particular views.

**condition** (*etag\_func=None, last\_modified\_func=None*)

**etag** (*etag\_func*)

**last\_modified** (*last\_modified\_func*)

These decorators can be used to generate ETag and Last-Modified headers; see *conditional view processing*.

## GZip compression

The decorators in `django.views.decorators.gzip` control content compression on a per-view basis.

**gzip\_page** ()

This decorator compresses content if the browser allows gzip compression. It sets the Vary header accordingly, so that caches will base their storage on the Accept-Encoding header.

## Vary headers

The decorators in `django.views.decorators.vary` can be used to control caching based on specific request headers.

**vary\_on\_cookie** (*func*)

**vary\_on\_headers** (*\*headers*)

The Vary header defines which request headers a cache mechanism should take into account when building its cache key.

See *using vary headers*.

## Caching

The decorators in `django.views.decorators.cache` control server and client-side caching.

**cache\_control** (*\*\*kwargs*)

This decorator patches the response's Cache-Control header by adding all of the keyword arguments to it. See `patch_cache_control()` for the details of the transformation.

**never\_cache** (*view\_func*)

This decorator adds a Cache-Control: max-age=0, no-cache, no-store, must-revalidate header to a response to indicate that a page should never be cached.

Before Django 1.9, Cache-Control: max-age=0 was sent. This didn't reliably prevent caching in all browsers.

### 3.3.4 File Uploads

When Django handles a file upload, the file data ends up placed in `request.FILES` (for more on the request object see the documentation for *request and response objects*). This document explains how files are stored on disk and in memory, and how to customize the default behavior.

**Warning:** There are security risks if you are accepting uploaded content from untrusted users! See the security guide's topic on *User-uploaded content* for mitigation details.

## Basic file uploads

Consider a simple form containing a `FileField`:

```
forms.py

from django import forms

class UploadFileForm(forms.Form):
    title = forms.CharField(max_length=50)
    file = forms.FileField()
```

A view handling this form will receive the file data in `request.FILES`, which is a dictionary containing a key for each `FileField` (or `ImageField`, or other `FileField` subclass) in the form. So the data from the above form would be accessible as `request.FILES['file']`.

Note that `request.FILES` will only contain data if the request method was POST and the `<form>` that posted the request has the attribute `enctype="multipart/form-data"`. Otherwise, `request.FILES` will be empty.

Most of the time, you'll simply pass the file data from `request` into the form as described in *Binding uploaded files to a form*. This would look something like:

```
views.py

from django.http import HttpResponseRedirect
from django.shortcuts import render
from .forms import UploadFileForm

# Imaginary function to handle an uploaded file.
from somewhere import handle_uploaded_file

def upload_file(request):
    if request.method == 'POST':
        form = UploadFileForm(request.POST, request.FILES)
        if form.is_valid():
            handle_uploaded_file(request.FILES['file'])
            return HttpResponseRedirect('/success/url/')
    else:
        form = UploadFileForm()
    return render(request, 'upload.html', {'form': form})
```

Notice that we have to pass `request.FILES` into the form's constructor; this is how file data gets bound into a form.

Here's a common way you might handle an uploaded file:

```
def handle_uploaded_file(f):
    with open('some/file/name.txt', 'wb+') as destination:
        for chunk in f.chunks():
            destination.write(chunk)
```

Looping over `UploadedFile.chunks()` instead of using `read()` ensures that large files don't overwhelm your system's memory.

There are a few other methods and attributes available on `UploadedFile` objects; see *UploadedFile* for a complete reference.

## Handling uploaded files with a model

If you're saving a file on a *Model* with a *FileField*, using a *ModelForm* makes this process much easier. The file object will be saved to the location specified by the *upload\_to* argument of the corresponding *FileField* when calling `form.save()`:

```
from django.http import HttpResponseRedirect
from django.shortcuts import render
from .forms import ModelFormWithFileField

def upload_file(request):
    if request.method == 'POST':
        form = ModelFormWithFileField(request.POST, request.FILES)
        if form.is_valid():
            # file is saved
            form.save()
            return HttpResponseRedirect('/success/url/')
    else:
        form = ModelFormWithFileField()
    return render(request, 'upload.html', {'form': form})
```

If you are constructing an object manually, you can simply assign the file object from `request.FILES` to the file field in the model:

```
from django.http import HttpResponseRedirect
from django.shortcuts import render
from .forms import UploadFileForm
from .models import ModelWithFileField

def upload_file(request):
    if request.method == 'POST':
        form = UploadFileForm(request.POST, request.FILES)
        if form.is_valid():
            instance = ModelWithFileField(file_field=request.FILES['file'])
            instance.save()
            return HttpResponseRedirect('/success/url/')
    else:
        form = UploadFileForm()
    return render(request, 'upload.html', {'form': form})
```

## Uploading multiple files

If you want to upload multiple files using one form field, set the `multiple` HTML attribute of field's widget:

```
forms.py
```

```
from django import forms
```

```
class FileFieldForm(forms.Form):
    file_field = forms.FileField(widget=forms.ClearableFileInput(attrs={'multiple': True}))
```

Then override the `post` method of your *FormView* subclass to handle multiple file uploads:

```
views.py
```

```
from django.views.generic.edit import FormView
from .forms import FileFieldForm
```

```
class FileFieldView(FormView):
    form_class = FileFieldForm
    template_name = 'upload.html' # Replace with your template.
    success_url = '...' # Replace with your URL or reverse().

    def post(self, request, *args, **kwargs):
        form_class = self.get_form_class()
        form = self.get_form(form_class)
        files = request.FILES.getlist('file_field')
        if form.is_valid():
            for f in files:
                ... # Do something with each file.
            return self.form_valid(form)
        else:
            return self.form_invalid(form)
```

## Upload Handlers

When a user uploads a file, Django passes off the file data to an *upload handler* – a small class that handles file data as it gets uploaded. Upload handlers are initially defined in the `FILE_UPLOAD_HANDLERS` setting, which defaults to:

```
["django.core.files.uploadhandler.MemoryFileUploadHandler",
 "django.core.files.uploadhandler.TemporaryFileUploadHandler"]
```

Together `MemoryFileUploadHandler` and `TemporaryFileUploadHandler` provide Django’s default file upload behavior of reading small files into memory and large ones onto disk.

You can write custom handlers that customize how Django handles files. You could, for example, use custom handlers to enforce user-level quotas, compress data on the fly, render progress bars, and even send data to another storage location directly without storing it locally. See *Writing custom upload handlers* for details on how you can customize or completely replace upload behavior.

## Where uploaded data is stored

Before you save uploaded files, the data needs to be stored somewhere.

By default, if an uploaded file is smaller than 2.5 megabytes, Django will hold the entire contents of the upload in memory. This means that saving the file involves only a read from memory and a write to disk and thus is very fast.

However, if an uploaded file is too large, Django will write the uploaded file to a temporary file stored in your system’s temporary directory. On a Unix-like platform this means you can expect Django to generate a file called something like `/tmp/tmpzfp6I6.upload`. If an upload is large enough, you can watch this file grow in size as Django streams the data onto disk.

These specifics – 2.5 megabytes; `/tmp`; etc. – are simply “reasonable defaults” which can be customized as described in the next section.

## Changing upload handler behavior

There are a few settings which control Django’s file upload behavior. See *File Upload Settings* for details.

## Modifying upload handlers on the fly

Sometimes particular views require different upload behavior. In these cases, you can override upload handlers on a per-request basis by modifying `request.upload_handlers`. By default, this list will contain the upload handlers given by `FILE_UPLOAD_HANDLERS`, but you can modify the list as you would any other list.

For instance, suppose you’ve written a `ProgressBarUploadHandler` that provides feedback on upload progress to some sort of AJAX widget. You’d add this handler to your upload handlers like this:

```
request.upload_handlers.insert(0, ProgressBarUploadHandler(request))
```

You’d probably want to use `list.insert()` in this case (instead of `append()`) because a progress bar handler would need to run *before* any other handlers. Remember, the upload handlers are processed in order.

If you want to replace the upload handlers completely, you can just assign a new list:

```
request.upload_handlers = [ProgressBarUploadHandler(request)]
```

**Note:** You can only modify upload handlers *before* accessing `request.POST` or `request.FILES` – it doesn’t make sense to change upload handlers after upload handling has already started. If you try to modify `request.upload_handlers` after reading from `request.POST` or `request.FILES` Django will throw an error.

Thus, you should always modify uploading handlers as early in your view as possible.

Also, `request.POST` is accessed by `CsrfViewMiddleware` which is enabled by default. This means you will need to use `csrf_exempt()` on your view to allow you to change the upload handlers. You will then need to use `csrf_protect()` on the function that actually processes the request. Note that this means that the handlers may start receiving the file upload before the CSRF checks have been done. Example code:

```
from django.views.decorators.csrf import csrf_exempt, csrf_protect

@csrf_exempt
def upload_file_view(request):
    request.upload_handlers.insert(0, ProgressBarUploadHandler(request))
    return _upload_file_view(request)

@csrf_protect
def _upload_file_view(request):
    ... # Process request
```

### 3.3.5 Django shortcut functions

The package `django.shortcuts` collects helper functions and classes that “span” multiple levels of MVC. In other words, these functions/classes introduce controlled coupling for convenience’s sake.

#### `render()`

**render** (*request, template\_name, context=None, content\_type=None, status=None, using=None*)

Combines a given template with a given context dictionary and returns an `HttpResponse` object with that rendered text.

Django does not provide a shortcut function which returns a `TemplateResponse` because the constructor of `TemplateResponse` offers the same level of convenience as `render()`.

## Required arguments

**request** The request object used to generate this response.

**template\_name** The full name of a template to use or sequence of template names. If a sequence is given, the first template that exists will be used. See the [template loading documentation](#) for more information on how templates are found.

## Optional arguments

**context** A dictionary of values to add to the template context. By default, this is an empty dictionary. If a value in the dictionary is callable, the view will call it just before rendering the template.

**content\_type** The MIME type to use for the resulting document. Defaults to the value of the `DEFAULT_CONTENT_TYPE` setting.

**status** The status code for the response. Defaults to 200.

**using** The *NAME* of a template engine to use for loading the template.

## Example

The following example renders the template `myapp/index.html` with the MIME type `application/xhtml+xml`:

```
from django.shortcuts import render

def my_view(request):
    # View code here...
    return render(request, 'myapp/index.html', {
        'foo': 'bar',
    }, content_type='application/xhtml+xml')
```

This example is equivalent to:

```
from django.http import HttpResponse
from django.template import loader

def my_view(request):
    # View code here...
    t = loader.get_template('myapp/index.html')
    c = {'foo': 'bar'}
    return HttpResponse(t.render(c, request), content_type='application/xhtml+xml')
```

## `render_to_response()`

**render\_to\_response** (*template\_name*, *context=None*, *content\_type=None*, *status=None*, *using=None*)

This function preceded the introduction of `render()` and works similarly except that it doesn't make the request available in the response. It's not recommended and is likely to be deprecated in the future.

## `redirect()`

**redirect** (*to*, *permanent=False*, *\*args*, *\*\*kwargs*)

Returns an `HttpResponseRedirect` to the appropriate URL for the arguments passed.

The arguments could be:

- A model: the model's `get_absolute_url()` function will be called.
- A view name, possibly with arguments: `reverse()` will be used to reverse-resolve the name.
- An absolute or relative URL, which will be used as-is for the redirect location.

By default issues a temporary redirect; pass `permanent=True` to issue a permanent redirect.

## Examples

You can use the `redirect()` function in a number of ways.

1. By passing some object; that object's `get_absolute_url()` method will be called to figure out the redirect URL:

```
from django.shortcuts import redirect

def my_view(request):
    ...
    object = MyModel.objects.get(...)
    return redirect(object)
```

2. By passing the name of a view and optionally some positional or keyword arguments; the URL will be reverse resolved using the `reverse()` method:

```
def my_view(request):
    ...
    return redirect('some-view-name', foo='bar')
```

3. By passing a hardcoded URL to redirect to:

```
def my_view(request):
    ...
    return redirect('/some/url/')
```

This also works with full URLs:

```
def my_view(request):
    ...
    return redirect('https://example.com/')
```

By default, `redirect()` returns a temporary redirect. All of the above forms accept a `permanent` argument; if set to `True` a permanent redirect will be returned:

```
def my_view(request):
    ...
    object = MyModel.objects.get(...)
    return redirect(object, permanent=True)
```

### `get_object_or_404()`

`get_object_or_404(klass, *args, **kwargs)`

Calls `get()` on a given model manager, but it raises `Http404` instead of the model's `DoesNotExist` exception.

## Required arguments

**klass** A *Model* class, a *Manager*, or a *QuerySet* instance from which to get the object.

**\*\*kwargs** Lookup parameters, which should be in the format accepted by `get()` and `filter()`.

## Example

The following example gets the object with the primary key of 1 from `MyModel`:

```
from django.shortcuts import get_object_or_404

def my_view(request):
    my_object = get_object_or_404(MyModel, pk=1)
```

This example is equivalent to:

```
from django.http import Http404

def my_view(request):
    try:
        my_object = MyModel.objects.get(pk=1)
    except MyModel.DoesNotExist:
        raise Http404("No MyModel matches the given query.")
```

The most common use case is to pass a *Model*, as shown above. However, you can also pass a *QuerySet* instance:

```
queryset = Book.objects.filter(title__startswith='M')
get_object_or_404(queryset, pk=1)
```

The above example is a bit contrived since it's equivalent to doing:

```
get_object_or_404(Book, title__startswith='M', pk=1)
```

but it can be useful if you are passed the `queryset` variable from somewhere else.

Finally, you can also use a *Manager*. This is useful for example if you have a *custom manager*:

```
get_object_or_404(Book.dahl_objects, title='Matilda')
```

You can also use *related managers*:

```
author = Author.objects.get(name='Roald Dahl')
get_object_or_404(author.book_set, title='Matilda')
```

Note: As with `get()`, a *MultipleObjectsReturned* exception will be raised if more than one object is found.

## `get_list_or_404()`

`get_list_or_404(klass, *args, **kwargs)`

Returns the result of `filter()` on a given model manager cast to a list, raising *Http404* if the resulting list is empty.

## Required arguments

**klass** A *Model*, *Manager* or *QuerySet* instance from which to get the list.

**\*\*kwargs** Lookup parameters, which should be in the format accepted by `get()` and `filter()`.

## Example

The following example gets all published objects from `MyModel`:

```

from django.shortcuts import get_list_or_404

def my_view(request):
    my_objects = get_list_or_404(MyModel, published=True)

```

This example is equivalent to:

```

from django.http import Http404

def my_view(request):
    my_objects = list(MyModel.objects.filter(published=True))
    if not my_objects:
        raise Http404("No MyModel matches the given query.")

```

## 3.3.6 Generic views

See *Built-in class-based views API*.

## 3.3.7 Middleware

Middleware is a framework of hooks into Django’s request/response processing. It’s a light, low-level “plugin” system for globally altering Django’s input or output.

Each middleware component is responsible for doing some specific function. For example, Django includes a middleware component, *AuthenticationMiddleware*, that associates users with requests using sessions.

This document explains how middleware works, how you activate middleware, and how to write your own middleware. Django ships with some built-in middleware you can use right out of the box. They’re documented in the *built-in middleware reference*.

A new style of middleware was introduced for use with the new `MIDDLEWARE` setting. If you’re using the old `MIDDLEWARE_CLASSES` setting, you’ll need to *adapt old, custom middleware* before using the new setting. This document describes new-style middleware. Refer to this page in older versions of the documentation for a description of how old-style middleware works.

### Writing your own middleware

A middleware factory is a callable that takes a `get_response` callable and returns a middleware. A middleware is a callable that takes a request and returns a response, just like a view.

A middleware can be written as a function that looks like this:

```
def simple_middleware(get_response):
    # One-time configuration and initialization.

    def middleware(request):
        # Code to be executed for each request before
        # the view (and later middleware) are called.

        response = get_response(request)

        # Code to be executed for each request/response after
        # the view is called.

        return response

    return middleware
```

Or it can be written as a class whose instances are callable, like this:

```
class SimpleMiddleware(object):
    def __init__(self, get_response):
        self.get_response = get_response
        # One-time configuration and initialization.

    def __call__(self, request):
        # Code to be executed for each request before
        # the view (and later middleware) are called.

        response = self.get_response(request)

        # Code to be executed for each request/response after
        # the view is called.

        return response
```

The `get_response` callable provided by Django might be the actual view (if this is the last listed middleware) or it might be the next middleware in the chain. The current middleware doesn't need to know or care what exactly it is, just that it represents whatever comes next.

The above is a slight simplification – the `get_response` callable for the last middleware in the chain won't be the actual view but rather a wrapper method from the handler which takes care of applying *view middleware*, calling the view with appropriate URL arguments, and applying *template-response* and *exception* middleware.

Middleware can live anywhere on your Python path.

### `__init__(get_response)`

Middleware factories must accept a `get_response` argument. You can also initialize some global state for the middleware. Keep in mind a couple of caveats:

- Django initializes your middleware with only the `get_response` argument, so you can't define `__init__()` as requiring any other arguments.
- Unlike the `__call__()` method which is called once per request, `__init__()` is called only *once*, when the Web server starts.

In older versions, `__init__()` wasn't called until the Web server responded to its first request.

In older versions, `__init__()` didn't accept any arguments. To allow your middleware to be used in Django 1.9 and earlier, make `get_response` an optional argument (`get_response=None`).

### Marking middleware as unused

It's sometimes useful to determine at startup time whether a piece of middleware should be used. In these cases, your middleware's `__init__()` method may raise `MiddlewareNotUsed`. Django will then remove that middleware from the middleware process and log a debug message to the `django.request` logger when `DEBUG` is `True`.

### Activating middleware

To activate a middleware component, add it to the `MIDDLEWARE` list in your Django settings.

In `MIDDLEWARE`, each middleware component is represented by a string: the full Python path to the middleware factory's class or function name. For example, here's the default value created by `django-admin startproject`:

```
MIDDLEWARE = [
    'django.middleware.security.SecurityMiddleware',
    'django.contrib.sessions.middleware.SessionMiddleware',
    'django.middleware.common.CommonMiddleware',
    'django.middleware.csrf.CsrfViewMiddleware',
    'django.contrib.auth.middleware.AuthenticationMiddleware',
    'django.contrib.messages.middleware.MessageMiddleware',
    'django.middleware.clickjacking.XFrameOptionsMiddleware',
]
```

A Django installation doesn't require any middleware — `MIDDLEWARE` can be empty, if you'd like — but it's strongly suggested that you at least use `CommonMiddleware`.

The order in `MIDDLEWARE` matters because a middleware can depend on other middleware. For instance, `AuthenticationMiddleware` stores the authenticated user in the session; therefore, it must run after `SessionMiddleware`. See *Middleware ordering* for some common hints about ordering of Django middleware classes.

### Middleware order and layering

During the request phase, before calling the view, Django applies middleware in the order it's defined in `MIDDLEWARE`, top-down.

You can think of it like an onion: each middleware class is a “layer” that wraps the view, which is in the core of the onion. If the request passes through all the layers of the onion (each one calls `get_response` to pass the request in to the next layer), all the way to the view at the core, the response will then pass through every layer (in reverse order) on the way back out.

If one of the layers decides to short-circuit and return a response without ever calling its `get_response`, none of the layers of the onion inside that layer (including the view) will see the request or the response. The response will only return through the same layers that the request passed in through.

### Other middleware hooks

Besides the basic request/response middleware pattern described earlier, you can add three other special methods to class-based middleware:

## `process_view()`

**process\_view** (*request*, *view\_func*, *view\_args*, *view\_kwargs*)

*request* is an `HttpRequest` object. *view\_func* is the Python function that Django is about to use. (It's the actual function object, not the name of the function as a string.) *view\_args* is a list of positional arguments that will be passed to the view, and *view\_kwargs* is a dictionary of keyword arguments that will be passed to the view. Neither *view\_args* nor *view\_kwargs* include the first view argument (*request*).

`process_view()` is called just before Django calls the view.

It should return either `None` or an `HttpResponse` object. If it returns `None`, Django will continue processing this request, executing any other `process_view()` middleware and, then, the appropriate view. If it returns an `HttpResponse` object, Django won't bother calling the appropriate view; it'll apply response middleware to that `HttpResponse` and return the result.

---

**Note:** Accessing `request.POST` inside middleware before the view runs or in `process_view()` will prevent any view running after the middleware from being able to *modify the upload handlers for the request*, and should normally be avoided.

The `CsrfViewMiddleware` class can be considered an exception, as it provides the `csrf_exempt()` and `csrf_protect()` decorators which allow views to explicitly control at what point the CSRF validation should occur.

---

## `process_exception()`

**process\_exception** (*request*, *exception*)

*request* is an `HttpRequest` object. *exception* is an `Exception` object raised by the view function.

Django calls `process_exception()` when a view raises an exception. `process_exception()` should return either `None` or an `HttpResponse` object. If it returns an `HttpResponse` object, the template response and response middleware will be applied and the resulting response returned to the browser. Otherwise, *default exception handling* kicks in.

Again, middleware are run in reverse order during the response phase, which includes `process_exception`. If an exception middleware returns a response, the `process_exception` methods of the middleware classes above that middleware won't be called at all.

## `process_template_response()`

**process\_template\_response** (*request*, *response*)

*request* is an `HttpRequest` object. *response* is the `TemplateResponse` object (or equivalent) returned by a Django view or by a middleware.

`process_template_response()` is called just after the view has finished executing, if the response instance has a `render()` method, indicating that it is a `TemplateResponse` or equivalent.

It must return a response object that implements a `render` method. It could alter the given response by changing `response.template_name` and `response.context_data`, or it could create and return a brand-new `TemplateResponse` or equivalent.

You don't need to explicitly render responses – responses will be automatically rendered once all template response middleware has been called.

Middleware are run in reverse order during the response phase, which includes `process_template_response()`.

### Dealing with streaming responses

Unlike `HttpResponse`, `StreamingHttpResponse` does not have a `content` attribute. As a result, middleware can no longer assume that all responses will have a `content` attribute. If they need access to the content, they must test for streaming responses and adjust their behavior accordingly:

```
if response.streaming:
    response.streaming_content = wrap_streaming_content(response.streaming_content)
else:
    response.content = alter_content(response.content)
```

---

**Note:** `streaming_content` should be assumed to be too large to hold in memory. Response middleware may wrap it in a new generator, but must not consume it. Wrapping is typically implemented as follows:

```
def wrap_streaming_content(content):
    for chunk in content:
        yield alter_content(chunk)
```

---

### Exception handling

Django automatically converts exceptions raised by the view or by middleware into an appropriate HTTP response with an error status code. *Certain exceptions* are converted to 4xx status codes, while an unknown exception is converted to a 500 status code.

This conversion takes place before and after each middleware (you can think of it as the thin film in between each layer of the onion), so that every middleware can always rely on getting some kind of HTTP response back from calling its `get_response` callable. Middleware don't need to worry about wrapping their call to `get_response` in a `try/except` and handling an exception that might have been raised by a later middleware or the view. Even if the very next middleware in the chain raises an `Http404` exception, for example, your middleware won't see that exception; instead it will get an `HttpResponse` object with a `status_code` of 404.

### Upgrading pre-Django 1.10-style middleware

```
class django.utils.deprecation.MiddlewareMixin
```

Django provides `django.utils.deprecation.MiddlewareMixin` to ease creating middleware classes that are compatible with both `MIDDLEWARE` and the old `MIDDLEWARE_CLASSES`. All middleware classes included with Django are compatible with both settings.

The mixin provides an `__init__()` method that accepts an optional `get_response` argument and stores it in `self.get_response`.

The `__call__()` method:

1. Calls `self.process_request(request)` (if defined).
2. Calls `self.get_response(request)` to get the response from later middleware and the view.
3. Calls `self.process_response(request, response)` (if defined).
4. Returns the response.

If used with `MIDDLEWARE_CLASSES`, the `__call__()` method will never be used; Django calls `process_request()` and `process_response()` directly.

In most cases, inheriting from this mixin will be sufficient to make an old-style middleware compatible with the new system with sufficient backwards-compatibility. The new short-circuiting semantics will be harmless or even beneficial to the existing middleware. In a few cases, a middleware class may need some changes to adjust to the new semantics.

These are the behavioral differences between using `MIDDLEWARE` and `MIDDLEWARE_CLASSES`:

1. Under `MIDDLEWARE_CLASSES`, every middleware will always have its `process_response` method called, even if an earlier middleware short-circuited by returning a response from its `process_request` method. Under `MIDDLEWARE`, middleware behaves more like an onion: the layers that a response goes through on the way out are the same layers that saw the request on the way in. If a middleware short-circuits, only that middleware and the ones before it in `MIDDLEWARE` will see the response.
2. Under `MIDDLEWARE_CLASSES`, `process_exception` is applied to exceptions raised from a middleware `process_request` method. Under `MIDDLEWARE`, `process_exception` applies only to exceptions raised from the view (or from the `render` method of a `TemplateResponse`). Exceptions raised from a middleware are converted to the appropriate HTTP response and then passed to the next middleware.
3. Under `MIDDLEWARE_CLASSES`, if a `process_response` method raises an exception, the `process_response` methods of all earlier middleware are skipped and a 500 Internal Server Error HTTP response is always returned (even if the exception raised was e.g. an `Http404`). Under `MIDDLEWARE`, an exception raised from a middleware will immediately be converted to the appropriate HTTP response, and then the next middleware in line will see that response. Middleware are never skipped due to a middleware raising an exception.

### 3.3.8 How to use sessions

Django provides full support for anonymous sessions. The session framework lets you store and retrieve arbitrary data on a per-site-visitor basis. It stores data on the server side and abstracts the sending and receiving of cookies. Cookies contain a session ID – not the data itself (unless you’re using the *cookie based backend*).

#### Enabling sessions

Sessions are implemented via a piece of *middleware*.

To enable session functionality, do the following:

- Edit the `MIDDLEWARE` setting and make sure it contains `'django.contrib.sessions.middleware.SessionMiddleware'`. The default `settings.py` created by `django-admin startproject` has `SessionMiddleware` activated.

If you don’t want to use sessions, you might as well remove the `SessionMiddleware` line from `MIDDLEWARE` and `'django.contrib.sessions'` from your `INSTALLED_APPS`. It’ll save you a small bit of overhead.

#### Configuring the session engine

By default, Django stores sessions in your database (using the model `django.contrib.sessions.models.Session`). Though this is convenient, in some setups it’s faster to store session data elsewhere, so Django can be configured to store session data on your filesystem or in your cache.

## Using database-backed sessions

If you want to use a database-backed session, you need to add `'django.contrib.sessions'` to your `INSTALLED_APPS` setting.

Once you have configured your installation, run `manage.py migrate` to install the single database table that stores session data.

## Using cached sessions

For better performance, you may want to use a cache-based session backend.

To store session data using Django's cache system, you'll first need to make sure you've configured your cache; see the [cache documentation](#) for details.

**Warning:** You should only use cache-based sessions if you're using the Memcached cache backend. The local-memory cache backend doesn't retain data long enough to be a good choice, and it'll be faster to use file or database sessions directly instead of sending everything through the file or database cache backends. Additionally, the local-memory cache backend is NOT multi-process safe, therefore probably not a good choice for production environments.

If you have multiple caches defined in `CACHES`, Django will use the default cache. To use another cache, set `SESSION_CACHE_ALIAS` to the name of that cache.

Once your cache is configured, you've got two choices for how to store data in the cache:

- Set `SESSION_ENGINE` to `"django.contrib.sessions.backends.cache"` for a simple caching session store. Session data will be stored directly in your cache. However, session data may not be persistent: cached data can be evicted if the cache fills up or if the cache server is restarted.
- For persistent, cached data, set `SESSION_ENGINE` to `"django.contrib.sessions.backends.cached_db"`. This uses a write-through cache – every write to the cache will also be written to the database. Session reads only use the database if the data is not already in the cache.

Both session stores are quite fast, but the simple cache is faster because it disregards persistence. In most cases, the `cached_db` backend will be fast enough, but if you need that last bit of performance, and are willing to let session data be expunged from time to time, the `cache` backend is for you.

If you use the `cached_db` session backend, you also need to follow the configuration instructions for the [using database-backed sessions](#).

## Using file-based sessions

To use file-based sessions, set the `SESSION_ENGINE` setting to `"django.contrib.sessions.backends.file"`.

You might also want to set the `SESSION_FILE_PATH` setting (which defaults to output from `tempfile.gettempdir()`, most likely `/tmp`) to control where Django stores session files. Be sure to check that your Web server has permissions to read and write to this location.

## Using cookie-based sessions

To use cookies-based sessions, set the `SESSION_ENGINE` setting to `"django.contrib.sessions.backends.signed_cookies"`. The session data will be stored using Django's tools for [cryptographic signing](#)

and the `SECRET_KEY` setting.

---

**Note:** It's recommended to leave the `SESSION_COOKIE_HTTPONLY` setting on `True` to prevent access to the stored data from JavaScript.

---

**Warning:** If the `SECRET_KEY` is not kept secret and you are using the `PickleSerializer`, this can lead to arbitrary remote code execution.

An attacker in possession of the `SECRET_KEY` can not only generate falsified session data, which your site will trust, but also remotely execute arbitrary code, as the data is serialized using pickle.

If you use cookie-based sessions, pay extra care that your secret key is always kept completely secret, for any system which might be remotely accessible.

#### The session data is signed but not encrypted

When using the cookies backend the session data can be read by the client.

A MAC (Message Authentication Code) is used to protect the data against changes by the client, so that the session data will be invalidated when being tampered with. The same invalidation happens if the client storing the cookie (e.g. your user's browser) can't store all of the session cookie and drops data. Even though Django compresses the data, it's still entirely possible to exceed the common limit of 4096 bytes per cookie.

#### No freshness guarantee

Note also that while the MAC can guarantee the authenticity of the data (that it was generated by your site, and not someone else), and the integrity of the data (that it is all there and correct), it cannot guarantee freshness i.e. that you are being sent back the last thing you sent to the client. This means that for some uses of session data, the cookie backend might open you up to [replay attacks](#). Unlike other session backends which keep a server-side record of each session and invalidate it when a user logs out, cookie-based sessions are not invalidated when a user logs out. Thus if an attacker steals a user's cookie, they can use that cookie to login as that user even if the user logs out. Cookies will only be detected as 'stale' if they are older than your `SESSION_COOKIE_AGE`.

#### Performance

Finally, the size of a cookie can have an impact on the [speed of your site](#).

## Using sessions in views

When `SessionMiddleware` is activated, each `HttpRequest` object – the first argument to any Django view function – will have a `session` attribute, which is a dictionary-like object.

You can read it and write to `request.session` at any point in your view. You can edit it multiple times.

#### class `backends.base.SessionBase`

This is the base class for all session objects. It has the following standard dictionary methods:

`__getitem__` (*key*)

Example: `fav_color = request.session['fav_color']`

`__setitem__` (*key, value*)

Example: `request.session['fav_color'] = 'blue'`

`__delitem__` (*key*)

Example: `del request.session['fav_color']`. This raises `KeyError` if the given key isn't already in the session.

**\_\_contains\_\_** (*key*)

Example: `'fav_color'` in `request.session`

**get** (*key, default=None*)

Example: `fav_color = request.session.get('fav_color', 'red')`

**pop** (*key, default=\_\_not\_given*)

Example: `fav_color = request.session.pop('fav_color', 'blue')`

**keys** ()

**items** ()

**setdefault** ()

**clear** ()

It also has these methods:

**flush** ()

Deletes the current session data from the session and deletes the session cookie. This is used if you want to ensure that the previous session data can't be accessed again from the user's browser (for example, the `django.contrib.auth.logout()` function calls it).

**set\_test\_cookie** ()

Sets a test cookie to determine whether the user's browser supports cookies. Due to the way cookies work, you won't be able to test this until the user's next page request. See [Setting test cookies](#) below for more information.

**test\_cookie\_worked** ()

Returns either `True` or `False`, depending on whether the user's browser accepted the test cookie. Due to the way cookies work, you'll have to call `set_test_cookie()` on a previous, separate page request. See [Setting test cookies](#) below for more information.

**delete\_test\_cookie** ()

Deletes the test cookie. Use this to clean up after yourself.

**set\_expiry** (*value*)

Sets the expiration time for the session. You can pass a number of different values:

- If *value* is an integer, the session will expire after that many seconds of inactivity. For example, calling `request.session.set_expiry(300)` would make the session expire in 5 minutes.
- If *value* is a `datetime` or `timedelta` object, the session will expire at that specific date/time. Note that `datetime` and `timedelta` values are only serializable if you are using the `PickleSerializer`.
- If *value* is 0, the user's session cookie will expire when the user's Web browser is closed.
- If *value* is `None`, the session reverts to using the global session expiry policy.

Reading a session is not considered activity for expiration purposes. Session expiration is computed from the last time the session was *modified*.

**get\_expiry\_age** ()

Returns the number of seconds until this session expires. For sessions with no custom expiration (or those set to expire at browser close), this will equal `SESSION_COOKIE_AGE`.

This function accepts two optional keyword arguments:

- `modification`: last modification of the session, as a `datetime` object. Defaults to the current time.

- `expiry`: expiry information for the session, as a `datetime` object, an `int` (in seconds), or `None`. Defaults to the value stored in the session by `set_expiry()`, if there is one, or `None`.

**get\_expiry\_date()**

Returns the date this session will expire. For sessions with no custom expiration (or those set to expire at browser close), this will equal the date `SESSION_COOKIE_AGE` seconds from now.

This function accepts the same keyword arguments as `get_expiry_age()`.

**get\_expire\_at\_browser\_close()**

Returns either `True` or `False`, depending on whether the user's session cookie will expire when the user's Web browser is closed.

**clear\_expired()**

Removes expired sessions from the session store. This class method is called by `clearsessions`.

**cycle\_key()**

Creates a new session key while retaining the current session data. `django.contrib.auth.login()` calls this method to mitigate against session fixation.

## Session serialization

By default, Django serializes session data using JSON. You can use the `SESSION_SERIALIZER` setting to customize the session serialization format. Even with the caveats described in *Write your own serializer*, we highly recommend sticking with JSON serialization *especially if you are using the cookie backend*.

For example, here's an attack scenario if you use `pickle` to serialize session data. If you're using the *signed cookie session backend* and `SECRET_KEY` is known by an attacker (there isn't an inherent vulnerability in Django that would cause it to leak), the attacker could insert a string into their session which, when unpickled, executes arbitrary code on the server. The technique for doing so is simple and easily available on the internet. Although the cookie session storage signs the cookie-stored data to prevent tampering, a `SECRET_KEY` leak immediately escalates to a remote code execution vulnerability.

## Bundled serializers

**class serializers.JSONSerializer**

A wrapper around the JSON serializer from `django.core.signing`. Can only serialize basic data types.

In addition, as JSON supports only string keys, note that using non-string keys in `request.session` won't work as expected:

```
>>> # initial assignment
>>> request.session[0] = 'bar'
>>> # subsequent requests following serialization & deserialization
>>> # of session data
>>> request.session[0] # KeyError
>>> request.session['0']
'bar'
```

Similarly, data that can't be encoded in JSON, such as non-UTF8 bytes like `'\xd9'` (which raises `UnicodeDecodeError`), can't be stored.

See the *Write your own serializer* section for more details on limitations of JSON serialization.

**class serializers.PickleSerializer**

Supports arbitrary Python objects, but, as described above, can lead to a remote code execution vulnerability if `SECRET_KEY` becomes known by an attacker.

## Write your own serializer

Note that unlike *PickleSerializer*, the *JSONSerializer* cannot handle arbitrary Python data types. As is often the case, there is a trade-off between convenience and security. If you wish to store more advanced data types including `datetime` and `Decimal` in JSON backed sessions, you will need to write a custom serializer (or convert such values to a JSON serializable object before storing them in `request.session`). While serializing these values is fairly straightforward (*DjangoJSONEncoder* may be helpful), writing a decoder that can reliably get back the same thing that you put in is more fragile. For example, you run the risk of returning a `datetime` that was actually a string that just happened to be in the same format chosen for `datetimes`).

Your serializer class must implement two methods, `dumps(self, obj)` and `loads(self, data)`, to serialize and deserialize the dictionary of session data, respectively.

## Session object guidelines

- Use normal Python strings as dictionary keys on `request.session`. This is more of a convention than a hard-and-fast rule.
- Session dictionary keys that begin with an underscore are reserved for internal use by Django.
- Don't override `request.session` with a new object, and don't access or set its attributes. Use it like a Python dictionary.

## Examples

This simplistic view sets a `has_commented` variable to `True` after a user posts a comment. It doesn't let a user post a comment more than once:

```
def post_comment(request, new_comment):
    if request.session.get('has_commented', False):
        return HttpResponseRedirect("You've already commented.")
    c = comments.Comment(comment=new_comment)
    c.save()
    request.session['has_commented'] = True
    return HttpResponseRedirect("Thanks for your comment!")
```

This simplistic view logs in a “member” of the site:

```
def login(request):
    m = Member.objects.get(username=request.POST['username'])
    if m.password == request.POST['password']:
        request.session['member_id'] = m.id
        return HttpResponseRedirect("You're logged in.")
    else:
        return HttpResponseRedirect("Your username and password didn't match.")
```

...And this one logs a member out, according to `login()` above:

```
def logout(request):
    try:
        del request.session['member_id']
    except KeyError:
        pass
    return HttpResponseRedirect("You're logged out.")
```

The standard `django.contrib.auth.logout()` function actually does a bit more than this to prevent inadvertent data leakage. It calls the `flush()` method of `request.session`. We are using this example as a demonstration of how to work with session objects, not as a full `logout()` implementation.

## Setting test cookies

As a convenience, Django provides an easy way to test whether the user's browser accepts cookies. Just call the `set_test_cookie()` method of `request.session` in a view, and call `test_cookie_worked()` in a subsequent view – not in the same view call.

This awkward split between `set_test_cookie()` and `test_cookie_worked()` is necessary due to the way cookies work. When you set a cookie, you can't actually tell whether a browser accepted it until the browser's next request.

It's good practice to use `delete_test_cookie()` to clean up after yourself. Do this after you've verified that the test cookie worked.

Here's a typical usage example:

```
from django.http import HttpResponseRedirect
from django.shortcuts import render

def login(request):
    if request.method == 'POST':
        if request.session.test_cookie_worked():
            request.session.delete_test_cookie()
            return HttpResponseRedirect("You're logged in.")
        else:
            return HttpResponseRedirect("Please enable cookies and try again.")
    request.session.set_test_cookie()
    return render(request, 'foo/login_form.html')
```

## Using sessions out of views

---

**Note:** The examples in this section import the `SessionStore` object directly from the `django.contrib.sessions.backends.db` backend. In your own code, you should consider importing `SessionStore` from the session engine designated by `SESSION_ENGINE`, as below:

```
>>> from importlib import import_module
>>> from django.conf import settings
>>> SessionStore = import_module(settings.SESSION_ENGINE).SessionStore
```

---

An API is available to manipulate session data outside of a view:

```
>>> from django.contrib.sessions.backends.db import SessionStore
>>> s = SessionStore()
>>> # stored as seconds since epoch since datetimes are not serializable in JSON.
>>> s['last_login'] = 1376587691
>>> s.create()
>>> s.session_key
'2b1189a188b44ad18c35e113ac6ceed'
>>> s = SessionStore(session_key='2b1189a188b44ad18c35e113ac6ceed')
>>> s['last_login']
1376587691
```

`SessionStore.create()` is designed to create a new session (i.e. one not loaded from the session store and with `session_key=None`). `save()` is designed to save an existing session (i.e. one loaded from the session store). Calling `save()` on a new session may also work but has a small chance of generating a `session_key` that collides with an existing one. `create()` calls `save()` and loops until an unused `session_key` is generated.

If you're using the `django.contrib.sessions.backends.db` backend, each session is just a normal Django model. The `Session` model is defined in `django/contrib/sessions/models.py`. Because it's a normal model, you can access sessions using the normal Django database API:

```
>>> from django.contrib.sessions.models import Session
>>> s = Session.objects.get(pk='2b1189a188b44ad18c35e113ac6ceead')
>>> s.expire_date
datetime.datetime(2005, 8, 20, 13, 35, 12)
```

Note that you'll need to call `get_decoded()` to get the session dictionary. This is necessary because the dictionary is stored in an encoded format:

```
>>> s.session_data
'KGRwMQpTJl9hdXRoX3VzZXJfaWQnCnAyCkxkxknMuMTEY2ZjODI2Yj...'
>>> s.get_decoded()
{'user_id': 42}
```

### When sessions are saved

By default, Django only saves to the session database when the session has been modified – that is if any of its dictionary values have been assigned or deleted:

```
# Session is modified.
request.session['foo'] = 'bar'

# Session is modified.
del request.session['foo']

# Session is modified.
request.session['foo'] = {}

# Gotcha: Session is NOT modified, because this alters
# request.session['foo'] instead of request.session.
request.session['foo']['bar'] = 'baz'
```

In the last case of the above example, we can tell the session object explicitly that it has been modified by setting the `modified` attribute on the session object:

```
request.session.modified = True
```

To change this default behavior, set the `SESSION_SAVE_EVERY_REQUEST` setting to `True`. When set to `True`, Django will save the session to the database on every single request.

Note that the session cookie is only sent when a session has been created or modified. If `SESSION_SAVE_EVERY_REQUEST` is `True`, the session cookie will be sent on every request.

Similarly, the `expires` part of a session cookie is updated each time the session cookie is sent.

The session is not saved if the response's status code is 500.

## Browser-length sessions vs. persistent sessions

You can control whether the session framework uses browser-length sessions vs. persistent sessions with the `SESSION_EXPIRE_AT_BROWSER_CLOSE` setting.

By default, `SESSION_EXPIRE_AT_BROWSER_CLOSE` is set to `False`, which means session cookies will be stored in users' browsers for as long as `SESSION_COOKIE_AGE`. Use this if you don't want people to have to log in every time they open a browser.

If `SESSION_EXPIRE_AT_BROWSER_CLOSE` is set to `True`, Django will use browser-length cookies – cookies that expire as soon as the user closes their browser. Use this if you want people to have to log in every time they open a browser.

This setting is a global default and can be overwritten at a per-session level by explicitly calling the `set_expiry()` method of `request.session` as described above in *using sessions in views*.

---

**Note:** Some browsers (Chrome, for example) provide settings that allow users to continue browsing sessions after closing and re-opening the browser. In some cases, this can interfere with the `SESSION_EXPIRE_AT_BROWSER_CLOSE` setting and prevent sessions from expiring on browser close. Please be aware of this while testing Django applications which have the `SESSION_EXPIRE_AT_BROWSER_CLOSE` setting enabled.

---

## Clearing the session store

As users create new sessions on your website, session data can accumulate in your session store. If you're using the database backend, the `django_session` database table will grow. If you're using the file backend, your temporary directory will contain an increasing number of files.

To understand this problem, consider what happens with the database backend. When a user logs in, Django adds a row to the `django_session` database table. Django updates this row each time the session data changes. If the user logs out manually, Django deletes the row. But if the user does *not* log out, the row never gets deleted. A similar process happens with the file backend.

Django does *not* provide automatic purging of expired sessions. Therefore, it's your job to purge expired sessions on a regular basis. Django provides a clean-up management command for this purpose: `clearsessions`. It's recommended to call this command on a regular basis, for example as a daily cron job.

Note that the cache backend isn't vulnerable to this problem, because caches automatically delete stale data. Neither is the cookie backend, because the session data is stored by the users' browsers.

## Settings

A few *Django settings* give you control over session behavior:

- `SESSION_CACHE_ALIAS`
- `SESSION_COOKIE_AGE`
- `SESSION_COOKIE_DOMAIN`
- `SESSION_COOKIE_HTTPONLY`
- `SESSION_COOKIE_NAME`
- `SESSION_COOKIE_PATH`
- `SESSION_COOKIE_SECURE`

- `SESSION_ENGINE`
- `SESSION_EXPIRE_AT_BROWSER_CLOSE`
- `SESSION_FILE_PATH`
- `SESSION_SAVE_EVERY_REQUEST`
- `SESSION_SERIALIZER`

## Session security

Subdomains within a site are able to set cookies on the client for the whole domain. This makes session fixation possible if cookies are permitted from subdomains not controlled by trusted users.

For example, an attacker could log into `good.example.com` and get a valid session for their account. If the attacker has control over `bad.example.com`, they can use it to send their session key to you since a subdomain is permitted to set cookies on `*.example.com`. When you visit `good.example.com`, you'll be logged in as the attacker and might inadvertently enter your sensitive personal data (e.g. credit card info) into the attacker's account.

Another possible attack would be if `good.example.com` sets its `SESSION_COOKIE_DOMAIN` to `".example.com"` which would cause session cookies from that site to be sent to `bad.example.com`.

## Technical details

- The session dictionary accepts any `json` serializable value when using `JSONSerializer` or any picklable Python object when using `PickleSerializer`. See the `pickle` module for more information.
- Session data is stored in a database table named `django_session`.
- Django only sends a cookie if it needs to. If you don't set any session data, it won't send a session cookie.

## The `SessionStore` object

When working with sessions internally, Django uses a session store object from the corresponding session engine. By convention, the session store object class is named `SessionStore` and is located in the module designated by `SESSION_ENGINE`.

All `SessionStore` classes available in Django inherit from `SessionBase` and implement data manipulation methods, namely:

- `exists()`
- `create()`
- `save()`
- `delete()`
- `load()`
- `clear_expired()`

In order to build a custom session engine or to customize an existing one, you may create a new class inheriting from `SessionBase` or any other existing `SessionStore` class.

Extending most of the session engines is quite straightforward, but doing so with database-backed session engines generally requires some extra effort (see the next section for details).

## Extending database-backed session engines

Creating a custom database-backed session engine built upon those included in Django (namely `db` and `cached_db`) may be done by inheriting `AbstractBaseSession` and either `SessionStore` class.

`AbstractBaseSession` and `BaseSessionManager` are importable from `django.contrib.sessions`. `base_session` so that they can be imported without including `django.contrib.sessions` in `INSTALLED_APPS`.

**class** `base_session.AbstractBaseSession`

The abstract base session model.

**session\_key**

Primary key. The field itself may contain up to 40 characters. The current implementation generates a 32-character string (a random sequence of digits and lowercase ASCII letters).

**session\_data**

A string containing an encoded and serialized session dictionary.

**expire\_date**

A datetime designating when the session expires.

Expired sessions are not available to a user, however, they may still be stored in the database until the `clearsessions` management command is run.

**classmethod** `get_session_store_class()`

Returns a session store class to be used with this session model.

**get\_decoded()**

Returns decoded session data.

Decoding is performed by the session store class.

You can also customize the model manager by subclassing `BaseSessionManager`:

**class** `base_session.BaseSessionManager`

**encode** (`session_dict`)

Returns the given session dictionary serialized and encoded as a string.

Encoding is performed by the session store class tied to a model class.

**save** (`session_key`, `session_dict`, `expire_date`)

Saves session data for a provided session key, or deletes the session in case the data is empty.

Customization of `SessionStore` classes is achieved by overriding methods and properties described below:

**class** `backends.db.SessionStore`

Implements database-backed session store.

**classmethod** `get_model_class()`

Override this method to return a custom session model if you need one.

**create\_model\_instance** (`data`)

Returns a new instance of the session model object, which represents the current session state.

Overriding this method provides the ability to modify session model data before it's saved to database.

**class** `backends.cached_db.SessionStore`

Implements cached database-backed session store.

**cache\_key\_prefix**

A prefix added to a session key to build a cache key string.

## Example

The example below shows a custom database-backed session engine that includes an additional database column to store an account ID (thus providing an option to query the database for all active sessions for an account):

```
from django.contrib.sessions.backends.db import SessionStore as DBStore
from django.contrib.sessions.base_session import AbstractBaseSession
from django.db import models

class CustomSession(AbstractBaseSession):
    account_id = models.IntegerField(null=True, db_index=True)

    @classmethod
    def get_session_store_class(cls):
        return SessionStore

class SessionStore(DBStore):
    @classmethod
    def get_model_class(cls):
        return CustomSession

    def create_model_instance(self, data):
        obj = super(SessionStore, self).create_model_instance(data)
        try:
            account_id = int(data.get('_auth_user_id'))
        except (ValueError, TypeError):
            account_id = None
        obj.account_id = account_id
        return obj
```

If you are migrating from the Django’s built-in `cached_db` session store to a custom one based on `cached_db`, you should override the cache key prefix in order to prevent a namespace clash:

```
class SessionStore(CachedDBStore):
    cache_key_prefix = 'mysessions.custom_cached_db_backend'

    # ...
```

## Session IDs in URLs

The Django sessions framework is entirely, and solely, cookie-based. It does not fall back to putting session IDs in URLs as a last resort, as PHP does. This is an intentional design decision. Not only does that behavior make URLs ugly, it makes your site vulnerable to session-ID theft via the “Referer” header.

## 3.4 Working with forms

### About this document

This document provides an introduction to the basics of web forms and how they are handled in Django. For a more detailed look at specific areas of the forms API, see *The Forms API*, *Form fields*, and *Form and field validation*.

Unless you’re planning to build websites and applications that do nothing but publish content, and don’t accept input from your visitors, you’re going to need to understand and use forms.

Django provides a range of tools and libraries to help you build forms to accept input from site visitors, and then process and respond to the input.

### 3.4.1 HTML forms

In HTML, a form is a collection of elements inside `<form> . . . </form>` that allow a visitor to do things like enter text, select options, manipulate objects or controls, and so on, and then send that information back to the server.

Some of these form interface elements - text input or checkboxes - are fairly simple and are built into HTML itself. Others are much more complex; an interface that pops up a date picker or allows you to move a slider or manipulate controls will typically use JavaScript and CSS as well as HTML form `<input>` elements to achieve these effects.

As well as its `<input>` elements, a form must specify two things:

- *where*: the URL to which the data corresponding to the user's input should be returned
- *how*: the HTTP method the data should be returned by

As an example, the login form for the Django admin contains several `<input>` elements: one of `type="text"` for the username, one of `type="password"` for the password, and one of `type="submit"` for the "Log in" button. It also contains some hidden text fields that the user doesn't see, which Django uses to determine what to do next.

It also tells the browser that the form data should be sent to the URL specified in the `<form>`'s `action` attribute - `/admin/` - and that it should be sent using the HTTP mechanism specified by the `method` attribute - `post`.

When the `<input type="submit" value="Log in">` element is triggered, the data is returned to `/admin/`.

### GET and POST

GET and POST are the only HTTP methods to use when dealing with forms.

Django's login form is returned using the POST method, in which the browser bundles up the form data, encodes it for transmission, sends it to the server, and then receives back its response.

GET, by contrast, bundles the submitted data into a string, and uses this to compose a URL. The URL contains the address where the data must be sent, as well as the data keys and values. You can see this in action if you do a search in the Django documentation, which will produce a URL of the form `https://docs.djangoproject.com/search/?q=forms&release=1`.

GET and POST are typically used for different purposes.

Any request that could be used to change the state of the system - for example, a request that makes changes in the database - should use POST. GET should be used only for requests that do not affect the state of the system.

GET would also be unsuitable for a password form, because the password would appear in the URL, and thus, also in browser history and server logs, all in plain text. Neither would it be suitable for large quantities of data, or for binary data, such as an image. A Web application that uses GET requests for admin forms is a security risk: it can be easy for an attacker to mimic a form's request to gain access to sensitive parts of the system. POST, coupled with other protections like Django's *CSRF protection* offers more control over access.

On the other hand, GET is suitable for things like a web search form, because the URLs that represent a GET request can easily be bookmarked, shared, or resubmitted.

### 3.4.2 Django's role in forms

Handling forms is a complex business. Consider Django's admin, where numerous items of data of several different types may need to be prepared for display in a form, rendered as HTML, edited using a convenient interface, returned

to the server, validated and cleaned up, and then saved or passed on for further processing.

Django’s form functionality can simplify and automate vast portions of this work, and can also do it more securely than most programmers would be able to do in code they wrote themselves.

Django handles three distinct parts of the work involved in forms:

- preparing and restructuring data to make it ready for rendering
- creating HTML forms for the data
- receiving and processing submitted forms and data from the client

It is *possible* to write code that does all of this manually, but Django can take care of it all for you.

### 3.4.3 Forms in Django

We’ve described HTML forms briefly, but an HTML `<form>` is just one part of the machinery required.

In the context of a Web application, ‘form’ might refer to that HTML `<form>`, or to the Django *Form* that produces it, or to the structured data returned when it is submitted, or to the end-to-end working collection of these parts.

#### The Django `Form` class

At the heart of this system of components is Django’s *Form* class. In much the same way that a Django model describes the logical structure of an object, its behavior, and the way its parts are represented to us, a *Form* class describes a form and determines how it works and appears.

In a similar way that a model class’s fields map to database fields, a form class’s fields map to HTML form `<input>` elements. (A *ModelForm* maps a model class’s fields to HTML form `<input>` elements via a *Form*; this is what the Django admin is based upon.)

A form’s fields are themselves classes; they manage form data and perform validation when a form is submitted. A *DateField* and a *FileField* handle very different kinds of data and have to do different things with it.

A form field is represented to a user in the browser as an HTML “widget” - a piece of user interface machinery. Each field type has an appropriate default *Widget class*, but these can be overridden as required.

#### Instantiating, processing, and rendering forms

When rendering an object in Django, we generally:

1. get hold of it in the view (fetch it from the database, for example)
2. pass it to the template context
3. expand it to HTML markup using template variables

Rendering a form in a template involves nearly the same work as rendering any other kind of object, but there are some key differences.

In the case of a model instance that contained no data, it would rarely if ever be useful to do anything with it in a template. On the other hand, it makes perfect sense to render an unpopulated form - that’s what we do when we want the user to populate it.

So when we handle a model instance in a view, we typically retrieve it from the database. When we’re dealing with a form we typically instantiate it in the view.

When we instantiate a form, we can opt to leave it empty or pre-populate it, for example with:

- data from a saved model instance (as in the case of admin forms for editing)

- data that we have collated from other sources
- data received from a previous HTML form submission

The last of these cases is the most interesting, because it's what makes it possible for users not just to read a website, but to send information back to it too.

### 3.4.4 Building a form

#### The work that needs to be done

Suppose you want to create a simple form on your website, in order to obtain the user's name. You'd need something like this in your template:

```
<form action="/your-name/" method="post">
  <label for="your_name">Your name: </label>
  <input id="your_name" type="text" name="your_name" value="{{ current_name }}">
  <input type="submit" value="OK">
</form>
```

This tells the browser to return the form data to the URL `/your-name/`, using the `POST` method. It will display a text field, labeled “Your name:”, and a button marked “OK”. If the template context contains a `current_name` variable, that will be used to pre-fill the `your_name` field.

You'll need a view that renders the template containing the HTML form, and that can supply the `current_name` field as appropriate.

When the form is submitted, the `POST` request which is sent to the server will contain the form data.

Now you'll also need a view corresponding to that `/your-name/` URL which will find the appropriate key/value pairs in the request, and then process them.

This is a very simple form. In practice, a form might contain dozens or hundreds of fields, many of which might need to be pre-populated, and we might expect the user to work through the edit-submit cycle several times before concluding the operation.

We might require some validation to occur in the browser, even before the form is submitted; we might want to use much more complex fields, that allow the user to do things like pick dates from a calendar and so on.

At this point it's much easier to get Django to do most of this work for us.

### Building a form in Django

#### The `Form` class

We already know what we want our HTML form to look like. Our starting point for it in Django is this:

```
forms.py

from django import forms

class NameForm(forms.Form):
    your_name = forms.CharField(label='Your name', max_length=100)
```

This defines a `Form` class with a single field (`your_name`). We've applied a human-friendly label to the field, which will appear in the `<label>` when it's rendered (although in this case, the `label` we specified is actually the same one that would be generated automatically if we had omitted it).

The field's maximum allowable length is defined by `max_length`. This does two things. It puts a `maxlength="100"` on the HTML `<input>` (so the browser should prevent the user from entering more than that number of characters in the first place). It also means that when Django receives the form back from the browser, it will validate the length of the data.

A `Form` instance has an `is_valid()` method, which runs validation routines for all its fields. When this method is called, if all fields contain valid data, it will:

- return `True`
- place the form's data in its `cleaned_data` attribute.

The whole form, when rendered for the first time, will look like:

```
<label for="your_name">Your name: </label>
<input id="your_name" type="text" name="your_name" maxlength="100" required />
```

Note that it **does not** include the `<form>` tags, or a submit button. We'll have to provide those ourselves in the template.

## The view

Form data sent back to a Django website is processed by a view, generally the same view which published the form. This allows us to reuse some of the same logic.

To handle the form we need to instantiate it in the view for the URL where we want it to be published:

```
views.py

from django.shortcuts import render
from django.http import HttpResponseRedirect

from .forms import NameForm

def get_name(request):
    # if this is a POST request we need to process the form data
    if request.method == 'POST':
        # create a form instance and populate it with data from the request:
        form = NameForm(request.POST)
        # check whether it's valid:
        if form.is_valid():
            # process the data in form.cleaned_data as required
            # ...
            # redirect to a new URL:
            return HttpResponseRedirect('/thanks/')

    # if a GET (or any other method) we'll create a blank form
    else:
        form = NameForm()

    return render(request, 'name.html', {'form': form})
```

If we arrive at this view with a GET request, it will create an empty form instance and place it in the template context to be rendered. This is what we can expect to happen the first time we visit the URL.

If the form is submitted using a POST request, the view will once again create a form instance and populate it with data from the request: `form = NameForm(request.POST)` This is called “binding data to the form” (it is now a *bound* form).

We call the form's `is_valid()` method; if it's not `True`, we go back to the template with the form. This time the form is no longer empty (*unbound*) so the HTML form will be populated with the data previously submitted, where it can be edited and corrected as required.

If `is_valid()` is `True`, we'll now be able to find all the validated form data in its `cleaned_data` attribute. We can use this data to update the database or do other processing before sending an HTTP redirect to the browser telling it where to go next.

## The template

We don't need to do much in our `name.html` template. The simplest example is:

```
<form action="/your-name/" method="post">
  {% csrf_token %}
  {{ form }}
  <input type="submit" value="Submit" />
</form>
```

All the form's fields and their attributes will be unpacked into HTML markup from that `{{ form }}` by Django's template language.

---

## Forms and Cross Site Request Forgery protection

Django ships with an easy-to-use *protection against Cross Site Request Forgeries*. When submitting a form via POST with CSRF protection enabled you must use the `csrf_token` template tag as in the preceding example. However, since CSRF protection is not directly tied to forms in templates, this tag is omitted from the following examples in this document.

---

## HTML5 input types and browser validation

If your form includes a `URLField`, an `EmailField` or any integer field type, Django will use the `url`, `email` and `number` HTML5 input types. By default, browsers may apply their own validation on these fields, which may be stricter than Django's validation. If you would like to disable this behavior, set the `novalidate` attribute on the `form` tag, or specify a different widget on the field, like `TextInput`.

---

We now have a working web form, described by a Django `Form`, processed by a view, and rendered as an HTML `<form>`.

That's all you need to get started, but the forms framework puts a lot more at your fingertips. Once you understand the basics of the process described above, you should be prepared to understand other features of the forms system and ready to learn a bit more about the underlying machinery.

## 3.4.5 More about Django `Form` classes

All form classes are created as subclasses of `django.forms.Form`, including the `ModelForm`, which you encounter in Django's admin.

---

### Models and Forms

In fact if your form is going to be used to directly add or edit a Django model, a `ModelForm` can save you a great deal of time, effort, and code, because it will build a form, along with the appropriate fields and their attributes, from a

Model class.

---

## Bound and unbound form instances

The distinction between *Bound and unbound forms* is important:

- An unbound form has no data associated with it. When rendered to the user, it will be empty or will contain default values.
- A bound form has submitted data, and hence can be used to tell if that data is valid. If an invalid bound form is rendered, it can include inline error messages telling the user what data to correct.

The form's `is_bound` attribute will tell you whether a form has data bound to it or not.

## More on fields

Consider a more useful form than our minimal example above, which we could use to implement “contact me” functionality on a personal website:

```
forms.py
from django import forms

class ContactForm(forms.Form):
    subject = forms.CharField(max_length=100)
    message = forms.CharField(widget=forms.Textarea)
    sender = forms.EmailField()
    cc_myself = forms.BooleanField(required=False)
```

Our earlier form used a single field, `your_name`, a *CharField*. In this case, our form has four fields: `subject`, `message`, `sender` and `cc_myself`. *CharField*, *EmailField* and *BooleanField* are just three of the available field types; a full list can be found in *Form fields*.

## Widgets

Each form field has a corresponding *Widget class*, which in turn corresponds to an HTML form widget such as `<input type="text">`.

In most cases, the field will have a sensible default widget. For example, by default, a *CharField* will have a *TextInput* widget, that produces an `<input type="text">` in the HTML. If you needed `<textarea>` instead, you'd specify the appropriate widget when defining your form field, as we have done for the `message` field.

## Field data

Whatever the data submitted with a form, once it has been successfully validated by calling `is_valid()` (and `is_valid()` has returned `True`), the validated form data will be in the `form.cleaned_data` dictionary. This data will have been nicely converted into Python types for you.

---

**Note:** You can still access the unvalidated data directly from `request.POST` at this point, but the validated data is better.

---

In the contact form example above, `cc_myself` will be a boolean value. Likewise, fields such as *IntegerField* and *FloatField* convert values to a Python `int` and `float` respectively.

Here's how the form data could be processed in the view that handles this form:

```
views.py

from django.core.mail import send_mail

if form.is_valid():
    subject = form.cleaned_data['subject']
    message = form.cleaned_data['message']
    sender = form.cleaned_data['sender']
    cc_myself = form.cleaned_data['cc_myself']

    recipients = ['info@example.com']
    if cc_myself:
        recipients.append(sender)

    send_mail(subject, message, sender, recipients)
    return HttpResponseRedirect('/thanks/')
```

---

**Tip:** For more on sending email from Django, see *Sending email*.

---

Some field types need some extra handling. For example, files that are uploaded using a form need to be handled differently (they can be retrieved from `request.FILES`, rather than `request.POST`). For details of how to handle file uploads with your form, see *Binding uploaded files to a form*.

### 3.4.6 Working with form templates

All you need to do to get your form into a template is to place the form instance into the template context. So if your form is called `form` in the context, `{{ form }}` will render its `<label>` and `<input>` elements appropriately.

#### Form rendering options

---

##### Additional form template furniture

Don't forget that a form's output does *not* include the surrounding `<form>` tags, or the form's submit control. You will have to provide these yourself.

---

There are other output options though for the `<label>/<input>` pairs:

- `{{ form.as_table }}` will render them as table cells wrapped in `<tr>` tags
- `{{ form.as_p }}` will render them wrapped in `<p>` tags
- `{{ form.as_ul }}` will render them wrapped in `<li>` tags

Note that you'll have to provide the surrounding `<table>` or `<ul>` elements yourself.

Here's the output of `{{ form.as_p }}` for our `ContactForm` instance:

```
<p><label for="id_subject">Subject:</label>
  <input id="id_subject" type="text" name="subject" maxlength="100" required /></p>
<p><label for="id_message">Message:</label>
  <textarea name="message" id="id_message" required></textarea></p>
<p><label for="id_sender">Sender:</label>
  <input type="email" name="sender" id="id_sender" required /></p>
```

```
<p><label for="id_cc_myself">Cc myself:</label>
  <input type="checkbox" name="cc_myself" id="id_cc_myself" /></p>
```

Note that each form field has an ID attribute set to `id_<field-name>`, which is referenced by the accompanying label tag. This is important in ensuring that forms are accessible to assistive technology such as screen reader software. You can also *customize the way in which labels and ids are generated*.

See *Outputting forms as HTML* for more on this.

## Rendering fields manually

We don't have to let Django unpack the form's fields; we can do it manually if we like (allowing us to reorder the fields, for example). Each field is available as an attribute of the form using `{{ form.name_of_field }}`, and in a Django template, will be rendered appropriately. For example:

```
{{ form.non_field_errors }}
<div class="fieldWrapper">
  {{ form.subject.errors }}
  <label for="{{ form.subject.id_for_label }}">Email subject:</label>
  {{ form.subject }}
</div>
<div class="fieldWrapper">
  {{ form.message.errors }}
  <label for="{{ form.message.id_for_label }}">Your message:</label>
  {{ form.message }}
</div>
<div class="fieldWrapper">
  {{ form.sender.errors }}
  <label for="{{ form.sender.id_for_label }}">Your email address:</label>
  {{ form.sender }}
</div>
<div class="fieldWrapper">
  {{ form.cc_myself.errors }}
  <label for="{{ form.cc_myself.id_for_label }}">CC yourself?</label>
  {{ form.cc_myself }}
</div>
```

Complete `<label>` elements can also be generated using the `label_tag()`. For example:

```
<div class="fieldWrapper">
  {{ form.subject.errors }}
  {{ form.subject.label_tag }}
  {{ form.subject }}
</div>
```

## Rendering form error messages

Of course, the price of this flexibility is more work. Until now we haven't had to worry about how to display form errors, because that's taken care of for us. In this example we have had to make sure we take care of any errors for each field and any errors for the form as a whole. Note `{{ form.non_field_errors }}` at the top of the form and the template lookup for errors on each field.

Using `{{ form.name_of_field.errors }}` displays a list of form errors, rendered as an unordered list. This might look like:

```
<ul class="errorlist">
  <li>Sender is required.</li>
</ul>
```

The list has a CSS class of `errorlist` to allow you to style its appearance. If you wish to further customize the display of errors you can do so by looping over them:

```
{% if form.subject.errors %}
<ol>
  {% for error in form.subject.errors %}
    <li><strong>{{ error|escape }}</strong></li>
  {% endfor %}
</ol>
{% endif %}
```

Non-field errors (and/or hidden field errors that are rendered at the top of the form when using helpers like `form.as_p()`) will be rendered with an additional class of `nonfield` to help distinguish them from field-specific errors. For example, `{{ form.non_field_errors }}` would look like:

```
<ul class="errorlist nonfield">
  <li>Generic validation error</li>
</ul>
```

See *The Forms API* for more on errors, styling, and working with form attributes in templates.

## Looping over the form's fields

If you're using the same HTML for each of your form fields, you can reduce duplicate code by looping through each field in turn using a `{% for %}` loop:

```
{% for field in form %}
  <div class="fieldWrapper">
    {{ field.errors }}
    {{ field.label_tag }} {{ field }}
    {% if field.help_text %}
      <p class="help">{{ field.help_text|safe }}</p>
    {% endif %}
  </div>
{% endfor %}
```

Useful attributes on `{{ field }}` include:

`{{ field.label }}` The label of the field, e.g. Email address.

`{{ field.label_tag }}` The field's label wrapped in the appropriate HTML `<label>` tag. This includes the form's `label_suffix`. For example, the default `label_suffix` is a colon:

```
<label for="id_email">Email address:</label>
```

`{{ field.id_for_label }}` The ID that will be used for this field (`id_email` in the example above). If you are constructing the label manually, you may want to use this in lieu of `label_tag`. It's also useful, for example, if you have some inline JavaScript and want to avoid hardcoding the field's ID.

`{{ field.value }}` The value of the field. e.g. `someone@example.com`.

`{{ field.html_name }}` The name of the field that will be used in the input element's name field. This takes the form prefix into account, if it has been set.

`{{ field.help_text }}` Any help text that has been associated with the field.

`{{ field.errors }}` Outputs a `<ul class="errorlist">` containing any validation errors corresponding to this field. You can customize the presentation of the errors with a `{% for error in field.errors %}` loop. In this case, each object in the loop is a simple string containing the error message.

`{{ field.is_hidden }}` This attribute is `True` if the form field is a hidden field and `False` otherwise. It's not particularly useful as a template variable, but could be useful in conditional tests such as:

```
{% if field.is_hidden %}
    {# Do something special #}
{% endif %}
```

`{{ field.field }}` The `Field` instance from the form class that this `BoundField` wraps. You can use it to access `Field` attributes, e.g. `{{ char_field.field.max_length }}`.

#### See also:

For a complete list of attributes and methods, see [BoundField](#).

### Looping over hidden and visible fields

If you're manually laying out a form in a template, as opposed to relying on Django's default form layout, you might want to treat `<input type="hidden">` fields differently from non-hidden fields. For example, because hidden fields don't display anything, putting error messages "next to" the field could cause confusion for your users – so errors for those fields should be handled differently.

Django provides two methods on a form that allow you to loop over the hidden and visible fields independently: `hidden_fields()` and `visible_fields()`. Here's a modification of an earlier example that uses these two methods:

```
{# Include the hidden fields #}
{% for hidden in form.hidden_fields %}
    {{ hidden }}
{% endfor %}
{# Include the visible fields #}
{% for field in form.visible_fields %}
    <div class="fieldWrapper">
        {{ field.errors }}
        {{ field.label_tag }} {{ field }}
    </div>
{% endfor %}
```

This example does not handle any errors in the hidden fields. Usually, an error in a hidden field is a sign of form tampering, since normal form interaction won't alter them. However, you could easily insert some error displays for those form errors, as well.

### Reusable form templates

If your site uses the same rendering logic for forms in multiple places, you can reduce duplication by saving the form's loop in a standalone template and using the `include` tag to reuse it in other templates:

```
# In your form template:
{% include "form_snippet.html" %}

# In form_snippet.html:
{% for field in form %}
```

```
<div class="fieldWrapper">
    {{ field.errors }}
    {{ field.label_tag }} {{ field }}
</div>
{% endfor %}
```

If the form object passed to a template has a different name within the context, you can alias it using the `with` argument of the `include` tag:

```
{% include "form_snippet.html" with form=comment_form %}
```

If you find yourself doing this often, you might consider creating a custom *inclusion tag*.

## 3.4.7 Further topics

This covers the basics, but forms can do a whole lot more:

### Formsets

#### class BaseFormSet

A formset is a layer of abstraction to work with multiple forms on the same page. It can be best compared to a data grid. Let's say you have the following form:

```
>>> from django import forms
>>> class ArticleForm(forms.Form):
...     title = forms.CharField()
...     pub_date = forms.DateField()
```

You might want to allow the user to create several articles at once. To create a formset out of an `ArticleForm` you would do:

```
>>> from django.forms import formset_factory
>>> ArticleFormSet = formset_factory(ArticleForm)
```

You now have created a formset named `ArticleFormSet`. The formset gives you the ability to iterate over the forms in the formset and display them as you would with a regular form:

```
>>> formset = ArticleFormSet()
>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↪ "form-0-title" id="id_form-0-title" /></td></tr>
<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-0-pub_date" id="id_form-0-pub_date" /></td></tr>
```

As you can see it only displayed one empty form. The number of empty forms that is displayed is controlled by the extra parameter. By default, `formset_factory()` defines one extra form; the following example will display two blank forms:

```
>>> ArticleFormSet = formset_factory(ArticleForm, extra=2)
```

Iterating over the `formset` will render the forms in the order they were created. You can change this order by providing an alternate implementation for the `__iter__()` method.

Formsets can also be indexed into, which returns the corresponding form. If you override `__iter__`, you will need to also override `__getitem__` to have matching behavior.

### Using initial data with a formset

Initial data is what drives the main usability of a formset. As shown above you can define the number of extra forms. What this means is that you are telling the formset how many additional forms to show in addition to the number of forms it generates from the initial data. Let's take a look at an example:

```
>>> import datetime
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, extra=2)
>>> formset = ArticleFormSet(initial=[
...     {'title': 'Django is now open source',
...     'pub_date': datetime.date.today(),}
... ])

>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↪ "form-0-title" value="Django is now open source" id="id_form-0-title" /></td></tr>
<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-0-pub_date" value="2008-05-12" id="id_form-0-pub_date" /></td></tr>
<tr><th><label for="id_form-1-title">Title:</label></th><td><input type="text" name=
↪ "form-1-title" id="id_form-1-title" /></td></tr>
<tr><th><label for="id_form-1-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-1-pub_date" id="id_form-1-pub_date" /></td></tr>
<tr><th><label for="id_form-2-title">Title:</label></th><td><input type="text" name=
↪ "form-2-title" id="id_form-2-title" /></td></tr>
<tr><th><label for="id_form-2-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-2-pub_date" id="id_form-2-pub_date" /></td></tr>
```

There are now a total of three forms showing above. One for the initial data that was passed in and two extra forms. Also note that we are passing in a list of dictionaries as the initial data.

If you use an initial for displaying a formset, you should pass the same `initial` when processing that formset's submission so that the formset can detect which forms were changed by the user. For example, you might have something like: `ArticleFormSet(request.POST, initial=[...])`.

#### See also:

*Creating formsets from models with model formsets.*

### Limiting the maximum number of forms

The `max_num` parameter to `formset_factory()` gives you the ability to limit the number of forms the formset will display:

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, extra=2, max_num=1)
>>> formset = ArticleFormSet()
>>> for form in formset:
...     print(form.as_table())
```

```
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↪ "form-0-title" id="id_form-0-title" /></td></tr>
<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-0-pub_date" id="id_form-0-pub_date" /></td></tr>
```

If the value of `max_num` is greater than the number of existing items in the initial data, up to `extra` additional blank forms will be added to the formset, so long as the total number of forms does not exceed `max_num`. For example, if `extra=2` and `max_num=2` and the formset is initialized with one `initial` item, a form for the initial item and one blank form will be displayed.

If the number of items in the initial data exceeds `max_num`, all initial data forms will be displayed regardless of the value of `max_num` and no extra forms will be displayed. For example, if `extra=3` and `max_num=1` and the formset is initialized with two initial items, two forms with the initial data will be displayed.

A `max_num` value of `None` (the default) puts a high limit on the number of forms displayed (1000). In practice this is equivalent to no limit.

By default, `max_num` only affects how many forms are displayed and does not affect validation. If `validate_max=True` is passed to the `formset_factory()`, then `max_num` will affect validation. See [validate\\_max](#).

## Formset validation

Validation with a formset is almost identical to a regular `Form`. There is an `is_valid` method on the formset to provide a convenient way to validate all forms in the formset:

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm)
>>> data = {
...     'form-TOTAL_FORMS': '1',
...     'form-INITIAL_FORMS': '0',
...     'form-MAX_NUM_FORMS': '',
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
True
```

We passed in no data to the formset which is resulting in a valid form. The formset is smart enough to ignore extra forms that were not changed. If we provide an invalid article:

```
>>> data = {
...     'form-TOTAL_FORMS': '2',
...     'form-INITIAL_FORMS': '0',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Test',
...     'form-0-pub_date': '1904-06-16',
...     'form-1-title': 'Test',
...     'form-1-pub_date': '', # <-- this date is missing but required
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
False
>>> formset.errors
[{}, {'pub_date': ['This field is required.']}]
```

As we can see, `formset.errors` is a list whose entries correspond to the forms in the formset. Validation was performed for each of the two forms, and the expected error message appears for the second item.

Just like when using a normal `Form`, each field in a formset's forms may include HTML attributes such as `maxlength` for browser validation. However, form fields of formsets won't include the `required` attribute as that validation may be incorrect when adding and deleting forms.

`BaseFormSet.total_error_count()`

To check how many errors there are in the formset, we can use the `total_error_count` method:

```
>>> # Using the previous example
>>> formset.errors
[{}, {'pub_date': ['This field is required.']]
>>> len(formset.errors)
2
>>> formset.total_error_count()
1
```

We can also check if form data differs from the initial data (i.e. the form was sent without any data):

```
>>> data = {
...     'form-TOTAL_FORMS': '1',
...     'form-INITIAL_FORMS': '0',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': '',
...     'form-0-pub_date': '',
... }
>>> formset = ArticleFormSet(data)
>>> formset.has_changed()
False
```

## Understanding the ManagementForm

You may have noticed the additional data (`form-TOTAL_FORMS`, `form-INITIAL_FORMS` and `form-MAX_NUM_FORMS`) that was required in the formset's data above. This data is required for the `ManagementForm`. This form is used by the formset to manage the collection of forms contained in the formset. If you don't provide this management data, an exception will be raised:

```
>>> data = {
...     'form-0-title': 'Test',
...     'form-0-pub_date': '',
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
Traceback (most recent call last):
...
django.forms.utils.ValidationError: ['ManagementForm data is missing or has been_
↳tampered with']
```

It is used to keep track of how many form instances are being displayed. If you are adding new forms via JavaScript, you should increment the count fields in this form as well. On the other hand, if you are using JavaScript to allow deletion of existing objects, then you need to ensure the ones being removed are properly marked for deletion by including `form-#-DELETE` in the POST data. It is expected that all forms are present in the POST data regardless.

The management form is available as an attribute of the formset itself. When rendering a formset in a template, you can include all the management data by rendering `{{ my_formset.management_form }}` (substituting the

name of your formset as appropriate).

### `total_form_count` and `initial_form_count`

`BaseFormSet` has a couple of methods that are closely related to the `ManagementForm`, `total_form_count` and `initial_form_count`.

`total_form_count` returns the total number of forms in this formset. `initial_form_count` returns the number of forms in the formset that were pre-filled, and is also used to determine how many forms are required. You will probably never need to override either of these methods, so please be sure you understand what they do before doing so.

### `empty_form`

`BaseFormSet` provides an additional attribute `empty_form` which returns a form instance with a prefix of `__prefix__` for easier use in dynamic forms with JavaScript.

## Custom formset validation

A formset has a `clean` method similar to the one on a `Form` class. This is where you define your own validation that works at the formset level:

```
>>> from django.forms import BaseFormSet
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm

>>> class BaseArticleFormSet(BaseFormSet):
...     def clean(self):
...         """Checks that no two articles have the same title."""
...         if any(self.errors):
...             # Don't bother validating the formset unless each form is valid on_
↳its own
...             return
...         titles = []
...         for form in self.forms:
...             title = form.cleaned_data['title']
...             if title in titles:
...                 raise forms.ValidationError("Articles in a set must have distinct_
↳titles.")
...             titles.append(title)

>>> ArticleFormSet = formset_factory(ArticleForm, formset=BaseArticleFormSet)
>>> data = {
...     'form-TOTAL_FORMS': '2',
...     'form-INITIAL_FORMS': '0',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Test',
...     'form-0-pub_date': '1904-06-16',
...     'form-1-title': 'Test',
...     'form-1-pub_date': '1912-06-23',
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
False
```

```
>>> formset.errors
[{}, {}]
>>> formset.non_form_errors()
['Articles in a set must have distinct titles.']
```

The `formset.clean` method is called after all the `Form.clean` methods have been called. The errors will be found using the `non_form_errors()` method on the formset.

### Validating the number of forms in a formset

Django provides a couple ways to validate the minimum or maximum number of submitted forms. Applications which need more customizable validation of the number of forms should use custom formset validation.

#### `validate_max`

If `validate_max=True` is passed to `formset_factory()`, validation will also check that the number of forms in the data set, minus those marked for deletion, is less than or equal to `max_num`.

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, max_num=1, validate_max=True)
>>> data = {
...     'form-TOTAL_FORMS': '2',
...     'form-INITIAL_FORMS': '0',
...     'form-MIN_NUM_FORMS': '',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Test',
...     'form-0-pub_date': '1904-06-16',
...     'form-1-title': 'Test 2',
...     'form-1-pub_date': '1912-06-23',
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
False
>>> formset.errors
[{}, {}]
>>> formset.non_form_errors()
['Please submit 1 or fewer forms.']
```

`validate_max=True` validates against `max_num` strictly even if `max_num` was exceeded because the amount of initial data supplied was excessive.

---

**Note:** Regardless of `validate_max`, if the number of forms in a data set exceeds `max_num` by more than 1000, then the form will fail to validate as if `validate_max` were set, and additionally only the first 1000 forms above `max_num` will be validated. The remainder will be truncated entirely. This is to protect against memory exhaustion attacks using forged POST requests.

---

#### `validate_min`

If `validate_min=True` is passed to `formset_factory()`, validation will also check that the number of forms in the data set, minus those marked for deletion, is greater than or equal to `min_num`.

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, min_num=3, validate_min=True)
>>> data = {
...     'form-TOTAL_FORMS': '2',
...     'form-INITIAL_FORMS': '0',
...     'form-MIN_NUM_FORMS': '',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Test',
...     'form-0-pub_date': '1904-06-16',
...     'form-1-title': 'Test 2',
...     'form-1-pub_date': '1912-06-23',
... }
>>> formset = ArticleFormSet(data)
>>> formset.is_valid()
False
>>> formset.errors
[{}, {}]
>>> formset.non_form_errors()
['Please submit 3 or more forms.']
```

## Dealing with ordering and deletion of forms

The `formset_factory()` provides two optional parameters `can_order` and `can_delete` to help with ordering of forms in formsets and deletion of forms from a formset.

### `can_order`

`BaseFormSet.can_order`

Default: `False`

Lets you create a formset with the ability to order:

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, can_order=True)
>>> formset = ArticleFormSet(initial=[
...     {'title': 'Article #1', 'pub_date': datetime.date(2008, 5, 10)},
...     {'title': 'Article #2', 'pub_date': datetime.date(2008, 5, 11)},
... ])
>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↪ "form-0-title" value="Article #1" id="id_form-0-title" /></td></tr>
<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-0-pub_date" value="2008-05-10" id="id_form-0-pub_date" /></td></tr>
<tr><th><label for="id_form-0-ORDER">Order:</label></th><td><input type="number" name=
↪ "form-0-ORDER" value="1" id="id_form-0-ORDER" /></td></tr>
<tr><th><label for="id_form-1-title">Title:</label></th><td><input type="text" name=
↪ "form-1-title" value="Article #2" id="id_form-1-title" /></td></tr>
<tr><th><label for="id_form-1-pub_date">Pub date:</label></th><td><input type="text"
↪ name="form-1-pub_date" value="2008-05-11" id="id_form-1-pub_date" /></td></tr>
<tr><th><label for="id_form-1-ORDER">Order:</label></th><td><input type="number" name=
↪ "form-1-ORDER" value="2" id="id_form-1-ORDER" /></td></tr>
```

```
<tr><th><label for="id_form-2-title">Title:</label></th><td><input type="text" name=
↵"form-2-title" id="id_form-2-title" /></td></tr>
<tr><th><label for="id_form-2-pub_date">Pub date:</label></th><td><input type="text"
↵name="form-2-pub_date" id="id_form-2-pub_date" /></td></tr>
<tr><th><label for="id_form-2-ORDER">Order:</label></th><td><input type="number" name=
↵"form-2-ORDER" id="id_form-2-ORDER" /></td></tr>
```

This adds an additional field to each form. This new field is named `ORDER` and is an `forms.IntegerField`. For the forms that came from the initial data it automatically assigned them a numeric value. Let's look at what will happen when the user changes these values:

```
>>> data = {
...     'form-TOTAL_FORMS': '3',
...     'form-INITIAL_FORMS': '2',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Article #1',
...     'form-0-pub_date': '2008-05-10',
...     'form-0-ORDER': '2',
...     'form-1-title': 'Article #2',
...     'form-1-pub_date': '2008-05-11',
...     'form-1-ORDER': '1',
...     'form-2-title': 'Article #3',
...     'form-2-pub_date': '2008-05-01',
...     'form-2-ORDER': '0',
... }

>>> formset = ArticleFormSet(data, initial=[
...     {'title': 'Article #1', 'pub_date': datetime.date(2008, 5, 10)},
...     {'title': 'Article #2', 'pub_date': datetime.date(2008, 5, 11)},
... ])
>>> formset.is_valid()
True
>>> for form in formset.ordered_forms:
...     print(form.cleaned_data)
{'pub_date': datetime.date(2008, 5, 1), 'ORDER': 0, 'title': 'Article #3'}
{'pub_date': datetime.date(2008, 5, 11), 'ORDER': 1, 'title': 'Article #2'}
{'pub_date': datetime.date(2008, 5, 10), 'ORDER': 2, 'title': 'Article #1'}
```

## can\_delete

`BaseFormSet.can_delete`

Default: `False`

Lets you create a formset with the ability to select forms for deletion:

```
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> ArticleFormSet = formset_factory(ArticleForm, can_delete=True)
>>> formset = ArticleFormSet(initial=[
...     {'title': 'Article #1', 'pub_date': datetime.date(2008, 5, 10)},
...     {'title': 'Article #2', 'pub_date': datetime.date(2008, 5, 11)},
... ])
>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↵"form-0-title" value="Article #1" id="id_form-0-title" /></td></tr>
```

```

<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↵ name="form-0-pub_date" value="2008-05-10" id="id_form-0-pub_date" /></td></tr>
<tr><th><label for="id_form-0-DELETE">Delete:</label></th><td><input type="checkbox"
↵ name="form-0-DELETE" id="id_form-0-DELETE" /></td></tr>
<tr><th><label for="id_form-1-title">Title:</label></th><td><input type="text" name=
↵ "form-1-title" value="Article #2" id="id_form-1-title" /></td></tr>
<tr><th><label for="id_form-1-pub_date">Pub date:</label></th><td><input type="text"
↵ name="form-1-pub_date" value="2008-05-11" id="id_form-1-pub_date" /></td></tr>
<tr><th><label for="id_form-1-DELETE">Delete:</label></th><td><input type="checkbox"
↵ name="form-1-DELETE" id="id_form-1-DELETE" /></td></tr>
<tr><th><label for="id_form-2-title">Title:</label></th><td><input type="text" name=
↵ "form-2-title" id="id_form-2-title" /></td></tr>
<tr><th><label for="id_form-2-pub_date">Pub date:</label></th><td><input type="text"
↵ name="form-2-pub_date" id="id_form-2-pub_date" /></td></tr>
<tr><th><label for="id_form-2-DELETE">Delete:</label></th><td><input type="checkbox"
↵ name="form-2-DELETE" id="id_form-2-DELETE" /></td></tr>

```

Similar to `can_order` this adds a new field to each form named `DELETE` and is a `forms.BooleanField`. When data comes through marking any of the delete fields you can access them with `deleted_forms`:

```

>>> data = {
...     'form-TOTAL_FORMS': '3',
...     'form-INITIAL_FORMS': '2',
...     'form-MAX_NUM_FORMS': '',
...     'form-0-title': 'Article #1',
...     'form-0-pub_date': '2008-05-10',
...     'form-0-DELETE': 'on',
...     'form-1-title': 'Article #2',
...     'form-1-pub_date': '2008-05-11',
...     'form-1-DELETE': '',
...     'form-2-title': '',
...     'form-2-pub_date': '',
...     'form-2-DELETE': '',
... }

>>> formset = ArticleFormSet(data, initial=[
...     {'title': 'Article #1', 'pub_date': datetime.date(2008, 5, 10)},
...     {'title': 'Article #2', 'pub_date': datetime.date(2008, 5, 11)},
... ])
>>> [form.cleaned_data for form in formset.deleted_forms]
[{'DELETE': True, 'pub_date': datetime.date(2008, 5, 10), 'title': 'Article #1'}]

```

If you are using a `ModelFormSet`, model instances for deleted forms will be deleted when you call `formset.save()`.

If you call `formset.save(commit=False)`, objects will not be deleted automatically. You'll need to call `delete()` on each of the `formset.deleted_objects` to actually delete them:

```

>>> instances = formset.save(commit=False)
>>> for obj in formset.deleted_objects:
...     obj.delete()

```

On the other hand, if you are using a plain `FormSet`, it's up to you to handle `formset.deleted_forms`, perhaps in your `formset.save()` method, as there's no general notion of what it means to delete a form.

## Adding additional fields to a formset

If you need to add additional fields to the formset this can be easily accomplished. The formset base class provides an `add_fields` method. You can simply override this method to add your own fields or even redefine the default fields/attributes of the order and deletion fields:

```
>>> from django.forms import BaseFormSet
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm
>>> class BaseArticleFormSet(BaseFormSet):
...     def add_fields(self, form, index):
...         super(BaseArticleFormSet, self).add_fields(form, index)
...         form.fields["my_field"] = forms.CharField()

>>> ArticleFormSet = formset_factory(ArticleForm, formset=BaseArticleFormSet)
>>> formset = ArticleFormSet()
>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-title">Title:</label></th><td><input type="text" name=
↵"form-0-title" id="id_form-0-title" /></td></tr>
<tr><th><label for="id_form-0-pub_date">Pub date:</label></th><td><input type="text"
↵name="form-0-pub_date" id="id_form-0-pub_date" /></td></tr>
<tr><th><label for="id_form-0-my_field">My field:</label></th><td><input type="text"
↵name="form-0-my_field" id="id_form-0-my_field" /></td></tr>
```

## Passing custom parameters to formset forms

Sometimes your form class takes custom parameters, like `MyArticleForm`. You can pass this parameter when instantiating the formset:

```
>>> from django.forms import BaseFormSet
>>> from django.forms import formset_factory
>>> from myapp.forms import ArticleForm

>>> class MyArticleForm(ArticleForm):
...     def __init__(self, *args, **kwargs):
...         self.user = kwargs.pop('user')
...         super(MyArticleForm, self).__init__(*args, **kwargs)

>>> ArticleFormSet = formset_factory(MyArticleForm)
>>> formset = ArticleFormSet(form_kwargs={'user': request.user})
```

The `form_kwargs` may also depend on the specific form instance. The formset base class provides a `get_form_kwargs` method. The method takes a single argument - the index of the form in the formset. The index is `None` for the *empty\_form*:

```
>>> from django.forms import BaseFormSet
>>> from django.forms import formset_factory

>>> class BaseArticleFormSet(BaseFormSet):
...     def get_form_kwargs(self, index):
...         kwargs = super(BaseArticleFormSet, self).get_form_kwargs(index)
...         kwargs['custom_kwarg'] = index
...         return kwargs
```

The `form_kwargs` argument was added.

## Using a formset in views and templates

Using a formset inside a view is as easy as using a regular `Form` class. The only thing you will want to be aware of is making sure to use the management form inside the template. Let's look at a sample view:

```
from django.forms import formset_factory
from django.shortcuts import render
from myapp.forms import ArticleForm

def manage_articles(request):
    ArticleFormSet = formset_factory(ArticleForm)
    if request.method == 'POST':
        formset = ArticleFormSet(request.POST, request.FILES)
        if formset.is_valid():
            # do something with the formset.cleaned_data
            pass
    else:
        formset = ArticleFormSet()
    return render(request, 'manage_articles.html', {'formset': formset})
```

The `manage_articles.html` template might look like this:

```
<form method="post" action="">
  {{ formset.management_form }}
  <table>
    {% for form in formset %}
      {{ form }}
    {% endfor %}
  </table>
</form>
```

However there's a slight shortcut for the above by letting the formset itself deal with the management form:

```
<form method="post" action="">
  <table>
    {{ formset }}
  </table>
</form>
```

The above ends up calling the `as_table` method on the formset class.

## Manually rendered `can_delete` and `can_order`

If you manually render fields in the template, you can render `can_delete` parameter with `{{ form.DELETE }}`:

```
<form method="post" action="">
  {{ formset.management_form }}
  {% for form in formset %}
    <ul>
      <li>{{ form.title }}</li>
      <li>{{ form.pub_date }}</li>
      {% if formset.can_delete %}
        <li>{{ form.DELETE }}</li>
      {% endif %}
    </ul>
  {% endfor %}
</form>
```

Similarly, if the formset has the ability to order (`can_order=True`), it is possible to render it with `{{ form.ORDER }}`.

### Using more than one formset in a view

You are able to use more than one formset in a view if you like. Formsets borrow much of its behavior from forms. With that said you are able to use `prefix` to prefix formset form field names with a given value to allow more than one formset to be sent to a view without name clashing. Lets take a look at how this might be accomplished:

```
from django.forms import formset_factory
from django.shortcuts import render
from myapp.forms import ArticleForm, BookForm

def manage_articles(request):
    ArticleFormSet = formset_factory(ArticleForm)
    BookFormSet = formset_factory(BookForm)
    if request.method == 'POST':
        article_formset = ArticleFormSet(request.POST, request.FILES, prefix='articles
↪')
        book_formset = BookFormSet(request.POST, request.FILES, prefix='books')
        if article_formset.is_valid() and book_formset.is_valid():
            # do something with the cleaned_data on the formsets.
            pass
    else:
        article_formset = ArticleFormSet(prefix='articles')
        book_formset = BookFormSet(prefix='books')
    return render(request, 'manage_articles.html', {
        'article_formset': article_formset,
        'book_formset': book_formset,
    })
```

You would then render the formsets as normal. It is important to point out that you need to pass `prefix` on both the POST and non-POST cases so that it is rendered and processed correctly.

### Creating forms from models

#### ModelForm

##### class ModelForm

If you're building a database-driven app, chances are you'll have forms that map closely to Django models. For instance, you might have a `BlogComment` model, and you want to create a form that lets people submit comments. In this case, it would be redundant to define the field types in your form, because you've already defined the fields in your model.

For this reason, Django provides a helper class that lets you create a `Form` class from a Django model.

For example:

```
>>> from django.forms import ModelForm
>>> from myapp.models import Article

# Create the form class.
>>> class ArticleForm(ModelForm):
```

```

...     class Meta:
...         model = Article
...         fields = ['pub_date', 'headline', 'content', 'reporter']

# Creating a form to add an article.
>>> form = ArticleForm()

# Creating a form to change an existing article.
>>> article = Article.objects.get(pk=1)
>>> form = ArticleForm(instance=article)

```

## Field types

The generated Form class will have a form field for every model field specified, in the order specified in the `fields` attribute.

Each model field has a corresponding default form field. For example, a `CharField` on a model is represented as a `CharField` on a form. A model `ManyToManyField` is represented as a `MultipleChoiceField`. Here is the full list of conversions:

Model field	Form field
<code>AutoField</code>	Not represented in the form
<code>BigAutoField</code>	Not represented in the form
<code>BigIntegerField</code>	<code>IntegerField</code> with <code>min_value</code> set to -9223372036854775808 and <code>max_value</code> set to 9223372036854775807.
<code>BooleanField</code>	<code>BooleanField</code>
<code>CharField</code>	<code>CharField</code> with <code>max_length</code> set to the model field's <code>max_length</code>
<code>CommaSeparatedIntegerField</code>	<code>CharField</code>
<code>DateField</code>	<code>DateField</code>
<code>DateTimeField</code>	<code>DateTimeField</code>
<code>DecimalField</code>	<code>DecimalField</code>
<code>EmailField</code>	<code>EmailField</code>
<code>FileField</code>	<code>FileField</code>
<code>FilePathField</code>	<code>FilePathField</code>
<code>FloatField</code>	<code>FloatField</code>
<code>ForeignKey</code>	<code>ModelChoiceField</code> (see below)
<code>ImageField</code>	<code>ImageField</code>
<code>IntegerField</code>	<code>IntegerField</code>
<code>IPAddressField</code>	<code>IPAddressField</code>
<code>GenericIPAddressField</code>	<code>GenericIPAddressField</code>
<code>ManyToManyField</code>	<code>ModelMultipleChoiceField</code> (see below)
<code>NullBooleanField</code>	<code>NullBooleanField</code>
<code>PositiveIntegerField</code>	<code>IntegerField</code>
<code>PositiveSmallIntegerField</code>	<code>IntegerField</code>
<code>SlugField</code>	<code>SlugField</code>
<code>SmallIntegerField</code>	<code>IntegerField</code>
<code>TextField</code>	<code>CharField</code> with <code>widget=forms.Textarea</code>
<code>TimeField</code>	<code>TimeField</code>
<code>URLField</code>	<code>URLField</code>

As you might expect, the `ForeignKey` and `ManyToManyField` model field types are special cases:

- `ForeignKey` is represented by `django.forms.ModelChoiceField`, which is a `ChoiceField` whose choices are a model `QuerySet`.

- `ManyToManyField` is represented by `django.forms.ModelMultipleChoiceField`, which is a `MultipleChoiceField` whose choices are a model `QuerySet`.

In addition, each generated form field has attributes set as follows:

- If the model field has `blank=True`, then `required` is set to `False` on the form field. Otherwise, `required=True`.
- The form field's `label` is set to the `verbose_name` of the model field, with the first character capitalized.
- The form field's `help_text` is set to the `help_text` of the model field.
- If the model field has `choices` set, then the form field's `widget` will be set to `Select`, with choices coming from the model field's `choices`. The choices will normally include the blank choice which is selected by default. If the field is required, this forces the user to make a selection. The blank choice will not be included if the model field has `blank=False` and an explicit default value (the default value will be initially selected instead).

Finally, note that you can override the form field used for a given model field. See *Overriding the default fields* below.

## A full example

Consider this set of models:

```
from django.db import models
from django.forms import ModelForm

TITLE_CHOICES = (
    ('MR', 'Mr.'),
    ('MRS', 'Mrs.'),
    ('MS', 'Ms.'),
)

class Author(models.Model):
    name = models.CharField(max_length=100)
    title = models.CharField(max_length=3, choices=TITLE_CHOICES)
    birth_date = models.DateField(blank=True, null=True)

    def __str__(self):
        return self.name  # __unicode__ on Python 2

class Book(models.Model):
    name = models.CharField(max_length=100)
    authors = models.ManyToManyField(Author)

class AuthorForm(ModelForm):
    class Meta:
        model = Author
        fields = ['name', 'title', 'birth_date']

class BookForm(ModelForm):
    class Meta:
        model = Book
        fields = ['name', 'authors']
```

With these models, the `ModelForm` subclasses above would be roughly equivalent to this (the only difference being the `save()` method, which we'll discuss in a moment.):

```
from django import forms

class AuthorForm(forms.Form):
    name = forms.CharField(max_length=100)
    title = forms.CharField(
        max_length=3,
        widget=forms.Select(choices=TITLE_CHOICES),
    )
    birth_date = forms.DateField(required=False)

class BookForm(forms.Form):
    name = forms.CharField(max_length=100)
    authors = forms.ModelMultipleChoiceField(queryset=Author.objects.all())
```

### Validation on a ModelForm

There are two main steps involved in validating a ModelForm:

1. *Validating the form*
2. *Validating the model instance*

Just like normal form validation, model form validation is triggered implicitly when calling `is_valid()` or accessing the `errors` attribute and explicitly when calling `full_clean()`, although you will typically not use the latter method in practice.

Model validation (`Model.full_clean()`) is triggered from within the form validation step, right after the form's `clean()` method is called.

**Warning:** The cleaning process modifies the model instance passed to the ModelForm constructor in various ways. For instance, any date fields on the model are converted into actual date objects. Failed validation may leave the underlying model instance in an inconsistent state and therefore it's not recommended to reuse it.

### Overriding the clean() method

You can override the `clean()` method on a model form to provide additional validation in the same way you can on a normal form.

A model form instance attached to a model object will contain an `instance` attribute that gives its methods access to that specific model instance.

**Warning:** The `ModelForm.clean()` method sets a flag that makes the *model validation* step validate the uniqueness of model fields that are marked as `unique`, `unique_together` or `unique_for_date|month|year`.

If you would like to override the `clean()` method and maintain this validation, you must call the parent class's `clean()` method.

## Interaction with model validation

As part of the validation process, `ModelForm` will call the `clean()` method of each field on your model that has a corresponding field on your form. If you have excluded any model fields, validation will not be run on those fields. See the [form validation](#) documentation for more on how field cleaning and validation work.

The model's `clean()` method will be called before any uniqueness checks are made. See [Validating objects](#) for more information on the model's `clean()` hook.

## Considerations regarding model's `error_messages`

Error messages defined at the *form field* level or at the *form Meta* level always take precedence over the error messages defined at the *model field* level.

Error messages defined on *model fields* are only used when the `ValidationError` is raised during the *model validation* step and no corresponding error messages are defined at the form level.

You can override the error messages from `NON_FIELD_ERRORS` raised by model validation by adding the `NON_FIELD_ERRORS` key to the `error_messages` dictionary of the `ModelForm`'s inner `Meta` class:

```
from django.forms import ModelForm
from django.core.exceptions import NON_FIELD_ERRORS

class ArticleForm(ModelForm):
    class Meta:
        error_messages = {
            NON_FIELD_ERRORS: {
                'unique_together': "%(model_name)s's %(field_labels)s are not unique.
↪",
            }
        }
```

## The `save()` method

Every `ModelForm` also has a `save()` method. This method creates and saves a database object from the data bound to the form. A subclass of `ModelForm` can accept an existing model instance as the keyword argument `instance`; if this is supplied, `save()` will update that instance. If it's not supplied, `save()` will create a new instance of the specified model:

```
>>> from myapp.models import Article
>>> from myapp.forms import ArticleForm

# Create a form instance from POST data.
>>> f = ArticleForm(request.POST)

# Save a new Article object from the form's data.
>>> new_article = f.save()

# Create a form to edit an existing Article, but use
# POST data to populate the form.
>>> a = Article.objects.get(pk=1)
>>> f = ArticleForm(request.POST, instance=a)
>>> f.save()
```

Note that if the form *hasn't been validated*, calling `save()` will do so by checking `form.errors`. A `ValueError` will be raised if the data in the form doesn't validate – i.e., if `form.errors` evaluates to `True`.

If an optional field doesn't appear in the form's data, the resulting model instance uses the model field `default`, if there is one, for that field. This behavior doesn't apply to fields that use `CheckboxInput`, `CheckboxSelectMultiple`, or `SelectMultiple` (or any custom widget whose `value_omitted_from_data()` method always returns `False`) since an unchecked checkbox and unselected `<select multiple>` don't appear in the data of an HTML form submission. Use a custom form field or widget if you're designing an API and want the default fallback behavior for a field that uses one of these widgets.

Older versions don't have the exception for `CheckboxInput` which means that unchecked checkboxes receive a value of `True` if that's the model field default.

The `value_omitted_from_data()` method was added.

This `save()` method accepts an optional `commit` keyword argument, which accepts either `True` or `False`. If you call `save()` with `commit=False`, then it will return an object that hasn't yet been saved to the database. In this case, it's up to you to call `save()` on the resulting model instance. This is useful if you want to do custom processing on the object before saving it, or if you want to use one of the specialized *model saving options*. `commit` is `True` by default.

Another side effect of using `commit=False` is seen when your model has a many-to-many relation with another model. If your model has a many-to-many relation and you specify `commit=False` when you save a form, Django cannot immediately save the form data for the many-to-many relation. This is because it isn't possible to save many-to-many data for an instance until the instance exists in the database.

To work around this problem, every time you save a form using `commit=False`, Django adds a `save_m2m()` method to your `ModelForm` subclass. After you've manually saved the instance produced by the form, you can invoke `save_m2m()` to save the many-to-many form data. For example:

```
# Create a form instance with POST data.
>>> f = AuthorForm(request.POST)

# Create, but don't save the new author instance.
>>> new_author = f.save(commit=False)

# Modify the author in some way.
>>> new_author.some_field = 'some_value'

# Save the new instance.
>>> new_author.save()

# Now, save the many-to-many data for the form.
>>> f.save_m2m()
```

Calling `save_m2m()` is only required if you use `save(commit=False)`. When you use a simple `save()` on a form, all data – including many-to-many data – is saved without the need for any additional method calls. For example:

```
# Create a form instance with POST data.
>>> a = Author()
>>> f = AuthorForm(request.POST, instance=a)

# Create and save the new author instance. There's no need to do anything else.
>>> new_author = f.save()
```

Other than the `save()` and `save_m2m()` methods, a `ModelForm` works exactly the same way as any other forms form. For example, the `is_valid()` method is used to check for validity, the `is_multipart()` method is used to determine whether a form requires multipart file upload (and hence whether `request.FILES` must be passed to the form), etc. See *Binding uploaded files to a form* for more information.

## Selecting the fields to use

It is strongly recommended that you explicitly set all fields that should be edited in the form using the `fields` attribute. Failure to do so can easily lead to security problems when a form unexpectedly allows a user to set certain fields, especially when new fields are added to a model. Depending on how the form is rendered, the problem may not even be visible on the web page.

The alternative approach would be to include all fields automatically, or blacklist only some. This fundamental approach is known to be much less secure and has led to serious exploits on major websites (e.g. [GitHub](#)).

There are, however, two shortcuts available for cases where you can guarantee these security concerns do not apply to you:

1. Set the `fields` attribute to the special value `'__all__'` to indicate that all fields in the model should be used. For example:

```
from django.forms import ModelForm

class AuthorForm(ModelForm):
    class Meta:
        model = Author
        fields = '__all__'
```

2. Set the `exclude` attribute of the `ModelForm`'s inner `Meta` class to a list of fields to be excluded from the form.

For example:

```
class PartialAuthorForm(ModelForm):
    class Meta:
        model = Author
        exclude = ['title']
```

Since the `Author` model has the 3 fields `name`, `title` and `birth_date`, this will result in the fields `name` and `birth_date` being present on the form.

If either of these are used, the order the fields appear in the form will be the order the fields are defined in the model, with `ManyToManyField` instances appearing last.

In addition, Django applies the following rule: if you set `editable=False` on the model field, *any* form created from the model via `ModelForm` will not include that field.

---

**Note:** Any fields not included in a form by the above logic will not be set by the form's `save()` method. Also, if you manually add the excluded fields back to the form, they will not be initialized from the model instance.

Django will prevent any attempt to save an incomplete model, so if the model does not allow the missing fields to be empty, and does not provide a default value for the missing fields, any attempt to `save()` a `ModelForm` with missing fields will fail. To avoid this failure, you must instantiate your model with initial values for the missing, but required fields:

```
author = Author(title='Mr')
form = PartialAuthorForm(request.POST, instance=author)
form.save()
```

Alternatively, you can use `save(commit=False)` and manually set any extra required fields:

```
form = PartialAuthorForm(request.POST)
author = form.save(commit=False)
```

```
author.title = 'Mr'  
author.save()
```

See the *section on saving forms* for more details on using `save(commit=False)`.

---

## Overriding the default fields

The default field types, as described in the *Field types* table above, are sensible defaults. If you have a `DateField` in your model, chances are you'd want that to be represented as a `DateField` in your form. But `ModelForm` gives you the flexibility of changing the form field for a given model.

To specify a custom widget for a field, use the `widgets` attribute of the inner `Meta` class. This should be a dictionary mapping field names to widget classes or instances.

For example, if you want the `CharField` for the `name` attribute of `Author` to be represented by a `<textarea>` instead of its default `<input type="text">`, you can override the field's widget:

```
from django.forms import ModelForm, Textarea  
from myapp.models import Author  
  
class AuthorForm(ModelForm):  
    class Meta:  
        model = Author  
        fields = ('name', 'title', 'birth_date')  
        widgets = {  
            'name': Textarea(attrs={'cols': 80, 'rows': 20}),  
        }
```

The `widgets` dictionary accepts either widget instances (e.g., `Textarea(...)`) or classes (e.g., `Textarea`).

Similarly, you can specify the `labels`, `help_texts` and `error_messages` attributes of the inner `Meta` class if you want to further customize a field.

For example if you wanted to customize the wording of all user facing strings for the `name` field:

```
from django.utils.translation import ugettext_lazy as _  
  
class AuthorForm(ModelForm):  
    class Meta:  
        model = Author  
        fields = ('name', 'title', 'birth_date')  
        labels = {  
            'name': _('Writer'),  
        }  
        help_texts = {  
            'name': _('Some useful help text.'),  
        }  
        error_messages = {  
            'name': {  
                'max_length': _("This writer's name is too long."),  
            },  
        }
```

You can also specify `field_classes` to customize the type of fields instantiated by the form.

For example, if you wanted to use `MySlugFormField` for the `slug` field, you could do the following:

```

from django.forms import ModelForm
from myapp.models import Article

class ArticleForm(ModelForm):
    class Meta:
        model = Article
        fields = ['pub_date', 'headline', 'content', 'reporter', 'slug']
        field_classes = {
            'slug': MySlugFormField,
        }

```

Finally, if you want complete control over of a field – including its type, validators, required, etc. – you can do this by declaratively specifying fields like you would in a regular `Form`.

If you want to specify a field’s validators, you can do so by defining the field declaratively and setting its `validators` parameter:

```

from django.forms import ModelForm, CharField
from myapp.models import Article

class ArticleForm(ModelForm):
    slug = CharField(validators=[validate_slug])

    class Meta:
        model = Article
        fields = ['pub_date', 'headline', 'content', 'reporter', 'slug']

```

The `Meta.field_classes` attribute was added.

---

**Note:** When you explicitly instantiate a form field like this, it is important to understand how `ModelForm` and regular `Form` are related.

`ModelForm` is a regular `Form` which can automatically generate certain fields. The fields that are automatically generated depend on the content of the `Meta` class and on which fields have already been defined declaratively. Basically, `ModelForm` will **only** generate fields that are **missing** from the form, or in other words, fields that weren’t defined declaratively.

Fields defined declaratively are left as-is, therefore any customizations made to `Meta` attributes such as `widgets`, `labels`, `help_texts`, or `error_messages` are ignored; these only apply to fields that are generated automatically.

Similarly, fields defined declaratively do not draw their attributes like `max_length` or `required` from the corresponding model. If you want to maintain the behavior specified in the model, you must set the relevant arguments explicitly when declaring the form field.

For example, if the `Article` model looks like this:

```

class Article(models.Model):
    headline = models.CharField(
        max_length=200,
        null=True,
        blank=True,
        help_text='Use puns liberally',
    )
    content = models.TextField()

```

and you want to do some custom validation for `headline`, while keeping the `blank` and `help_text` values as specified, you might define `ArticleForm` like this:

```
class ArticleForm(ModelForm):
    headline = MyFormField(
        max_length=200,
        required=False,
        help_text='Use puns liberally',
    )

    class Meta:
        model = Article
        fields = ['headline', 'content']
```

You must ensure that the type of the form field can be used to set the contents of the corresponding model field. When they are not compatible, you will get a `ValueError` as no implicit conversion takes place.

See the [form field documentation](#) for more information on fields and their arguments.

---

### Enabling localization of fields

By default, the fields in a `ModelForm` will not localize their data. To enable localization for fields, you can use the `localized_fields` attribute on the `Meta` class.

```
>>> from django.forms import ModelForm
>>> from myapp.models import Author
>>> class AuthorForm(ModelForm):
...     class Meta:
...         model = Author
...         localized_fields = ('birth_date',)
```

If `localized_fields` is set to the special value `'__all__'`, all fields will be localized.

### Form inheritance

As with basic forms, you can extend and reuse `ModelForms` by inheriting them. This is useful if you need to declare extra fields or extra methods on a parent class for use in a number of forms derived from models. For example, using the previous `ArticleForm` class:

```
>>> class EnhancedArticleForm(ArticleForm):
...     def clean_pub_date(self):
...         ...
```

This creates a form that behaves identically to `ArticleForm`, except there's some extra validation and cleaning for the `pub_date` field.

You can also subclass the parent's `Meta` inner class if you want to change the `Meta.fields` or `Meta.exclude` lists:

```
>>> class RestrictedArticleForm(EnhancedArticleForm):
...     class Meta(ArticleForm.Meta):
...         exclude = ('body',)
```

This adds the extra method from the `EnhancedArticleForm` and modifies the original `ArticleForm.Meta` to remove one field.

There are a couple of things to note, however.

- Normal Python name resolution rules apply. If you have multiple base classes that declare a `Meta` inner class, only the first one will be used. This means the child's `Meta`, if it exists, otherwise the `Meta` of the first parent, etc.
- It's possible to inherit from both `Form` and `ModelForm` simultaneously, however, you must ensure that `ModelForm` appears first in the MRO. This is because these classes rely on different metaclasses and a class can only have one metaclass.
- It's possible to declaratively remove a `Field` inherited from a parent class by setting the name to be `None` on the subclass.

You can only use this technique to opt out from a field defined declaratively by a parent class; it won't prevent the `ModelForm` metaclass from generating a default field. To opt-out from default fields, see [Selecting the fields to use](#).

## Providing initial values

As with regular forms, it's possible to specify initial data for forms by specifying an `initial` parameter when instantiating the form. Initial values provided this way will override both initial values from the form field and values from an attached model instance. For example:

```
>>> article = Article.objects.get(pk=1)
>>> article.headline
'My headline'
>>> form = ArticleForm(initial={'headline': 'Initial headline'}, instance=article)
>>> form['headline'].value()
'Initial headline'
```

## ModelForm factory function

You can create forms from a given model using the standalone function `modelform_factory()`, instead of using a class definition. This may be more convenient if you do not have many customizations to make:

```
>>> from django.forms import modelform_factory
>>> from myapp.models import Book
>>> BookForm = modelform_factory(Book, fields=("author", "title"))
```

This can also be used to make simple modifications to existing forms, for example by specifying the widgets to be used for a given field:

```
>>> from django.forms import Textarea
>>> Form = modelform_factory(Book, form=BookForm,
...                          widgets={"title": Textarea()})
```

The fields to include can be specified using the `fields` and `exclude` keyword arguments, or the corresponding attributes on the `ModelForm` inner `Meta` class. Please see the `ModelForm` [Selecting the fields to use](#) documentation.

... or enable localization for specific fields:

```
>>> Form = modelform_factory(Author, form=AuthorForm, localized_fields=("birth_date",
↪))
```

## Model formsets

`class models.BaseModelFormSet`

Like *regular formsets*, Django provides a couple of enhanced formset classes that make it easy to work with Django models. Let's reuse the Author model from above:

```
>>> from django.forms import modelformset_factory
>>> from myapp.models import Author
>>> AuthorFormSet = modelformset_factory(Author, fields=('name', 'title'))
```

Using `fields` restricts the formset to use only the given fields. Alternatively, you can take an “opt-out” approach, specifying which fields to exclude:

```
>>> AuthorFormSet = modelformset_factory(Author, exclude=('birth_date',))
```

This will create a formset that is capable of working with the data associated with the Author model. It works just like a regular formset:

```
>>> formset = AuthorFormSet()
>>> print(formset)
<input type="hidden" name="form-TOTAL_FORMS" value="1" id="id_form-TOTAL_FORMS" />
↪<input type="hidden" name="form-INITIAL_FORMS" value="0" id="id_form-INITIAL_FORMS" />
↪</input type="hidden" name="form-MAX_NUM_FORMS" id="id_form-MAX_NUM_FORMS" />
<tr><th><label for="id_form-0-name">Name:</label></th><td><input id="id_form-0-name"
↪type="text" name="form-0-name" maxlength="100" /></td></tr>
<tr><th><label for="id_form-0-title">Title:</label></th><td><select name="form-0-title"
↪ id="id_form-0-title">
<option value="" selected="selected">-----</option>
<option value="MR">Mr.</option>
<option value="MRS">Mrs.</option>
<option value="MS">Ms.</option>
</select><input type="hidden" name="form-0-id" id="id_form-0-id" /></td></tr>
```

---

**Note:** `modelformset_factory()` uses `formset_factory()` to generate formsets. This means that a model formset is just an extension of a basic formset that knows how to interact with a particular model.

---

## Changing the queryset

By default, when you create a formset from a model, the formset will use a queryset that includes all objects in the model (e.g., `Author.objects.all()`). You can override this behavior by using the `queryset` argument:

```
>>> formset = AuthorFormSet(queryset=Author.objects.filter(name__startswith='O'))
```

Alternatively, you can create a subclass that sets `self.queryset` in `__init__`:

```
from django.forms import BaseModelFormSet
from myapp.models import Author

class BaseAuthorFormSet(BaseModelFormSet):
    def __init__(self, *args, **kwargs):
        super(BaseAuthorFormSet, self).__init__(*args, **kwargs)
        self.queryset = Author.objects.filter(name__startswith='O')
```

Then, pass your `BaseAuthorFormSet` class to the factory function:

```
>>> AuthorFormSet = modelformset_factory(
...     Author, fields=('name', 'title'), formset=BaseAuthorFormSet)
```

If you want to return a formset that doesn't include *any* pre-existing instances of the model, you can specify an empty `QuerySet`:

```
>>> AuthorFormSet(queryset=Author.objects.none())
```

## Changing the form

By default, when you use `modelformset_factory`, a model form will be created using `modelform_factory()`. Often, it can be useful to specify a custom model form. For example, you can create a custom model form that has custom validation:

```
class AuthorForm(forms.ModelForm):
    class Meta:
        model = Author
        fields = ('name', 'title')

    def clean_name(self):
        # custom validation for the name field
        ...
```

Then, pass your model form to the factory function:

```
AuthorFormSet = modelformset_factory(Author, form=AuthorForm)
```

It is not always necessary to define a custom model form. The `modelformset_factory` function has several arguments which are passed through to `modelform_factory`, which are described below.

## Specifying widgets to use in the form with `widgets`

Using the `widgets` parameter, you can specify a dictionary of values to customize the `ModelForm`'s widget class for a particular field. This works the same way as the `widgets` dictionary on the inner `Meta` class of a `ModelForm` works:

```
>>> AuthorFormSet = modelformset_factory(
...     Author, fields=('name', 'title'),
...     widgets={'name': Textarea(attrs={'cols': 80, 'rows': 20})})
```

## Enabling localization for fields with `localized_fields`

Using the `localized_fields` parameter, you can enable localization for fields in the form.

```
>>> AuthorFormSet = modelformset_factory(
...     Author, fields=('name', 'title', 'birth_date'),
...     localized_fields=('birth_date',))
```

If `localized_fields` is set to the special value `'__all__'`, all fields will be localized.

## Providing initial values

As with regular formsets, it's possible to *specify initial data* for forms in the formset by specifying an `initial` parameter when instantiating the model formset class returned by `modelformset_factory()`. However, with model formsets, the initial values only apply to extra forms, those that aren't attached to an existing model instance. If the extra forms with initial data aren't changed by the user, they won't be validated or saved.

## Saving objects in the formset

As with a `ModelForm`, you can save the data as a model object. This is done with the formset's `save()` method:

```
# Create a formset instance with POST data.
>>> formset = AuthorFormSet(request.POST)

# Assuming all is valid, save the data.
>>> instances = formset.save()
```

The `save()` method returns the instances that have been saved to the database. If a given instance's data didn't change in the bound data, the instance won't be saved to the database and won't be included in the return value (`instances`, in the above example).

When fields are missing from the form (for example because they have been excluded), these fields will not be set by the `save()` method. You can find more information about this restriction, which also holds for regular `ModelForms`, in *Selecting the fields to use*.

Pass `commit=False` to return the unsaved model instances:

```
# don't save to the database
>>> instances = formset.save(commit=False)
>>> for instance in instances:
...     # do something with instance
...     instance.save()
```

This gives you the ability to attach data to the instances before saving them to the database. If your formset contains a `ManyToManyField`, you'll also need to call `formset.save_m2m()` to ensure the many-to-many relationships are saved properly.

After calling `save()`, your model formset will have three new attributes containing the formset's changes:

`models.BaseModelFormSet.changed_objects`

`models.BaseModelFormSet.deleted_objects`

`models.BaseModelFormSet.new_objects`

## Limiting the number of editable objects

As with regular formsets, you can use the `max_num` and `extra` parameters to `modelformset_factory()` to limit the number of extra forms displayed.

`max_num` does not prevent existing objects from being displayed:

```
>>> Author.objects.order_by('name')
<QuerySet [<Author: Charles Baudelaire>, <Author: Paul Verlaine>, <Author: Walt_
↪Whitman]>

>>> AuthorFormSet = modelformset_factory(Author, fields=('name',), max_num=1)
```

```
>>> formset = AuthorFormSet(queryset=Author.objects.order_by('name'))
>>> [x.name for x in formset.get_queryset()]
['Charles Baudelaire', 'Paul Verlaine', 'Walt Whitman']
```

Also, `extra=0` doesn't prevent creation of new model instances as you can *add additional forms with JavaScript* or just send additional POST data. Formsets *don't yet provide functionality* for an “edit only” view that prevents creation of new instances.

If the value of `max_num` is greater than the number of existing related objects, up to `extra` additional blank forms will be added to the formset, so long as the total number of forms does not exceed `max_num`:

```
>>> AuthorFormSet = modelformset_factory(Author, fields=('name',), max_num=4, extra=2)
>>> formset = AuthorFormSet(queryset=Author.objects.order_by('name'))
>>> for form in formset:
...     print(form.as_table())
<tr><th><label for="id_form-0-name">Name:</label></th><td><input id="id_form-0-name"
↳type="text" name="form-0-name" value="Charles Baudelaire" maxlength="100" /><input
↳type="hidden" name="form-0-id" value="1" id="id_form-0-id" /></td></tr>
<tr><th><label for="id_form-1-name">Name:</label></th><td><input id="id_form-1-name"
↳type="text" name="form-1-name" value="Paul Verlaine" maxlength="100" /><input type=
↳"hidden" name="form-1-id" value="3" id="id_form-1-id" /></td></tr>
<tr><th><label for="id_form-2-name">Name:</label></th><td><input id="id_form-2-name"
↳type="text" name="form-2-name" value="Walt Whitman" maxlength="100" /><input type=
↳"hidden" name="form-2-id" value="2" id="id_form-2-id" /></td></tr>
<tr><th><label for="id_form-3-name">Name:</label></th><td><input id="id_form-3-name"
↳type="text" name="form-3-name" maxlength="100" /><input type="hidden" name="form-3-
↳id" id="id_form-3-id" /></td></tr>
```

A `max_num` value of `None` (the default) puts a high limit on the number of forms displayed (1000). In practice this is equivalent to no limit.

### Using a model formset in a view

Model formsets are very similar to formsets. Let's say we want to present a formset to edit `Author` model instances:

```
from django.forms import modelformset_factory
from django.shortcuts import render
from myapp.models import Author

def manage_authors(request):
    AuthorFormSet = modelformset_factory(Author, fields=('name', 'title'))
    if request.method == 'POST':
        formset = AuthorFormSet(request.POST, request.FILES)
        if formset.is_valid():
            formset.save()
            # do something.
    else:
        formset = AuthorFormSet()
    return render(request, 'manage_authors.html', {'formset': formset})
```

As you can see, the view logic of a model formset isn't drastically different than that of a “normal” formset. The only difference is that we call `formset.save()` to save the data into the database. (This was described above, in *Saving objects in the formset*.)

## Overriding `clean()` on a `ModelFormSet`

Just like with `ModelForms`, by default the `clean()` method of a `ModelFormSet` will validate that none of the items in the formset violate the unique constraints on your model (either `unique`, `unique_together` or `unique_for_date|month|year`). If you want to override the `clean()` method on a `ModelFormSet` and maintain this validation, you must call the parent class's `clean` method:

```
from django.forms import BaseModelFormSet

class MyModelFormSet(BaseModelFormSet):
    def clean(self):
        super(MyModelFormSet, self).clean()
        # example custom validation across forms in the formset
        for form in self.forms:
            # your custom formset validation
            ...
```

Also note that by the time you reach this step, individual model instances have already been created for each `Form`. Modifying a value in `form.cleaned_data` is not sufficient to affect the saved value. If you wish to modify a value in `ModelFormSet.clean()` you must modify `form.instance`:

```
from django.forms import BaseModelFormSet

class MyModelFormSet(BaseModelFormSet):
    def clean(self):
        super(MyModelFormSet, self).clean()

        for form in self.forms:
            name = form.cleaned_data['name'].upper()
            form.cleaned_data['name'] = name
            # update the instance value.
            form.instance.name = name
```

## Using a custom queryset

As stated earlier, you can override the default queryset used by the model formset:

```
from django.forms import modelformset_factory
from django.shortcuts import render
from myapp.models import Author

def manage_authors(request):
    AuthorFormSet = modelformset_factory(Author, fields=('name', 'title'))
    if request.method == "POST":
        formset = AuthorFormSet(
            request.POST, request.FILES,
            queryset=Author.objects.filter(name__startswith='O'),
        )
        if formset.is_valid():
            formset.save()
            # Do something.
    else:
        formset = AuthorFormSet(queryset=Author.objects.filter(name__startswith='O'))
    return render(request, 'manage_authors.html', {'formset': formset})
```

Note that we pass the `queryset` argument in both the `POST` and `GET` cases in this example.

## Using the formset in the template

There are three ways to render a formset in a Django template.

First, you can let the formset do most of the work:

```
<form method="post" action="">
    {{ formset }}
</form>
```

Second, you can manually render the formset, but let the form deal with itself:

```
<form method="post" action="">
    {{ formset.management_form }}
    {% for form in formset %}
        {{ form }}
    {% endfor %}
</form>
```

When you manually render the forms yourself, be sure to render the management form as shown above. See the [management form documentation](#).

Third, you can manually render each field:

```
<form method="post" action="">
    {{ formset.management_form }}
    {% for form in formset %}
        {% for field in form %}
            {{ field.label_tag }} {{ field }}
        {% endfor %}
    {% endfor %}
</form>
```

If you opt to use this third method and you don't iterate over the fields with a `{% for %}` loop, you'll need to render the primary key field. For example, if you were rendering the name and age fields of a model:

```
<form method="post" action="">
    {{ formset.management_form }}
    {% for form in formset %}
        {{ form.id }}
        <ul>
            <li>{{ form.name }}</li>
            <li>{{ form.age }}</li>
        </ul>
    {% endfor %}
</form>
```

Notice how we need to explicitly render `{{ form.id }}`. This ensures that the model formset, in the POST case, will work correctly. (This example assumes a primary key named `id`. If you've explicitly defined your own primary key that isn't called `id`, make sure it gets rendered.)

## Inline formsets

`class models.BaseInlineFormSet`

Inline formsets is a small abstraction layer on top of model formsets. These simplify the case of working with related objects via a foreign key. Suppose you have these two models:

```
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=100)

class Book(models.Model):
    author = models.ForeignKey(Author, on_delete=models.CASCADE)
    title = models.CharField(max_length=100)
```

If you want to create a formset that allows you to edit books belonging to a particular author, you could do this:

```
>>> from django.forms import inlineformset_factory
>>> BookFormSet = inlineformset_factory(Author, Book, fields=('title',))
>>> author = Author.objects.get(name='Mike Royko')
>>> formset = BookFormSet(instance=author)
```

---

**Note:** `inlineformset_factory()` uses `modelformset_factory()` and marks `can_delete=True`.

---

**See also:**

*Manually rendered `can_delete` and `can_order`.*

### Overriding methods on an `InlineFormSet`

When overriding methods on `InlineFormSet`, you should subclass `BaseInlineFormSet` rather than `BaseModelFormSet`.

For example, if you want to override `clean()`:

```
from django.forms import BaseInlineFormSet

class CustomInlineFormSet(BaseInlineFormSet):
    def clean(self):
        super(CustomInlineFormSet, self).clean()
        # example custom validation across forms in the formset
        for form in self.forms:
            # your custom formset validation
            ...
```

See also *Overriding `clean()` on a `ModelFormSet`.*

Then when you create your inline formset, pass in the optional argument `formset`:

```
>>> from django.forms import inlineformset_factory
>>> BookFormSet = inlineformset_factory(Author, Book, fields=('title',),
...     formset=CustomInlineFormSet)
>>> author = Author.objects.get(name='Mike Royko')
>>> formset = BookFormSet(instance=author)
```

### More than one foreign key to the same model

If your model contains more than one foreign key to the same model, you'll need to resolve the ambiguity manually using `fk_name`. For example, consider the following model:

```
class Friendship(models.Model):
    from_friend = models.ForeignKey(
        Friend,
        on_delete=models.CASCADE,
        related_name='from_friends',
    )
    to_friend = models.ForeignKey(
        Friend,
        on_delete=models.CASCADE,
        related_name='friends',
    )
    length_in_months = models.IntegerField()
```

To resolve this, you can use `fk_name` to `inlineformset_factory()`:

```
>>> FriendshipFormSet = inlineformset_factory(Friend, Friendship, fk_name='from_friend
↵',
...     fields=('to_friend', 'length_in_months'))
```

## Using an inline formset in a view

You may want to provide a view that allows a user to edit the related objects of a model. Here’s how you can do that:

```
def manage_books(request, author_id):
    author = Author.objects.get(pk=author_id)
    BookInlineFormSet = inlineformset_factory(Author, Book, fields=('title',))
    if request.method == "POST":
        formset = BookInlineFormSet(request.POST, request.FILES, instance=author)
        if formset.is_valid():
            formset.save()
            # Do something. Should generally end with a redirect. For example:
            return HttpResponseRedirect(author.get_absolute_url())
    else:
        formset = BookInlineFormSet(instance=author)
    return render(request, 'manage_books.html', {'formset': formset})
```

Notice how we pass `instance` in both the POST and GET cases.

## Specifying widgets to use in the inline form

`inlineformset_factory` uses `modelformset_factory` and passes most of its arguments to `modelformset_factory`. This means you can use the `widgets` parameter in much the same way as passing it to `modelformset_factory`. See [Specifying widgets to use in the form with widgets](#) above.

## Form Assets (the Media class)

Rendering an attractive and easy-to-use Web form requires more than just HTML - it also requires CSS stylesheets, and if you want to use fancy “Web2.0” widgets, you may also need to include some JavaScript on each page. The exact combination of CSS and JavaScript that is required for any given page will depend upon the widgets that are in use on that page.

This is where asset definitions come in. Django allows you to associate different files – like stylesheets and scripts – with the forms and widgets that require those assets. For example, if you want to use a calendar to render `DateFields`,

you can define a custom Calendar widget. This widget can then be associated with the CSS and JavaScript that is required to render the calendar. When the Calendar widget is used on a form, Django is able to identify the CSS and JavaScript files that are required, and provide the list of file names in a form suitable for easy inclusion on your Web page.

---

### Assets and Django Admin

The Django Admin application defines a number of customized widgets for calendars, filtered selections, and so on. These widgets define asset requirements, and the Django Admin uses the custom widgets in place of the Django defaults. The Admin templates will only include those files that are required to render the widgets on any given page.

If you like the widgets that the Django Admin application uses, feel free to use them in your own application! They're all stored in `django.contrib.admin.widgets`.

---

---

### Which JavaScript toolkit?

Many JavaScript toolkits exist, and many of them include widgets (such as calendar widgets) that can be used to enhance your application. Django has deliberately avoided blessing any one JavaScript toolkit. Each toolkit has its own relative strengths and weaknesses - use whichever toolkit suits your requirements. Django is able to integrate with any JavaScript toolkit.

---

### Assets as a static definition

The easiest way to define assets is as a static definition. Using this method, the declaration is an inner `Media` class. The properties of the inner class define the requirements.

Here's a simple example:

```
from django import forms

class CalendarWidget(forms.TextInput):
    class Media:
        css = {
            'all': ('pretty.css',)
        }
        js = ('animations.js', 'actions.js')
```

This code defines a `CalendarWidget`, which will be based on `TextInput`. Every time the `CalendarWidget` is used on a form, that form will be directed to include the CSS file `pretty.css`, and the JavaScript files `animations.js` and `actions.js`.

This static definition is converted at runtime into a widget property named `media`. The list of assets for a `CalendarWidget` instance can be retrieved through this property:

```
>>> w = CalendarWidget()
>>> print(w.media)
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>
```

Here's a list of all possible `Media` options. There are no required options.

## css

A dictionary describing the CSS files required for various forms of output media.

The values in the dictionary should be a tuple/list of file names. See [the section on paths](#) for details of how to specify paths to these files.

The keys in the dictionary are the output media types. These are the same types accepted by CSS files in media declarations: 'all', 'aural', 'braille', 'embossed', 'handheld', 'print', 'projection', 'screen', 'tty' and 'tv'. If you need to have different stylesheets for different media types, provide a list of CSS files for each output medium. The following example would provide two CSS options – one for the screen, and one for print:

```
class Media:
    css = {
        'screen': ('pretty.css',),
        'print': ('newspaper.css',)
    }
```

If a group of CSS files are appropriate for multiple output media types, the dictionary key can be a comma separated list of output media types. In the following example, TV's and projectors will have the same media requirements:

```
class Media:
    css = {
        'screen': ('pretty.css',),
        'tv,projector': ('lo_res.css',),
        'print': ('newspaper.css',)
    }
```

If this last CSS definition were to be rendered, it would become the following HTML:

```
<link href="http://static.example.com/pretty.css" type="text/css" media="screen" rel=
↪"stylesheet" />
<link href="http://static.example.com/lo_res.css" type="text/css" media="tv,projector
↪" rel="stylesheet" />
<link href="http://static.example.com/newspaper.css" type="text/css" media="print"
↪rel="stylesheet" />
```

## js

A tuple describing the required JavaScript files. See [the section on paths](#) for details of how to specify paths to these files.

## extend

A boolean defining inheritance behavior for `Media` declarations.

By default, any object using a static `Media` definition will inherit all the assets associated with the parent widget. This occurs regardless of how the parent defines its own requirements. For example, if we were to extend our basic `Calendar` widget from the example above:

```
>>> class FancyCalendarWidget(CalendarWidget):
...     class Media:
...         css = {
...             'all': ('fancy.css',)
...         }
```

```
...         js = ('whizbang.js',)

>>> w = FancyCalendarWidget()
>>> print(w.media)
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↳"stylesheet" />
<link href="http://static.example.com/fancy.css" type="text/css" media="all" rel=
↳"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>
<script type="text/javascript" src="http://static.example.com/whizbang.js"></script>
```

The `FancyCalendar` widget inherits all the assets from its parent widget. If you don't want `Media` to be inherited in this way, add an `extend=False` declaration to the `Media` declaration:

```
>>> class FancyCalendarWidget(CalendarWidget):
...     class Media:
...         extend = False
...         css = {
...             'all': ('fancy.css',)
...         }
...         js = ('whizbang.js',)

>>> w = FancyCalendarWidget()
>>> print(w.media)
<link href="http://static.example.com/fancy.css" type="text/css" media="all" rel=
↳"stylesheet" />
<script type="text/javascript" src="http://static.example.com/whizbang.js"></script>
```

If you require even more control over inheritance, define your assets using a *dynamic property*. Dynamic properties give you complete control over which files are inherited, and which are not.

### Media as a dynamic property

If you need to perform some more sophisticated manipulation of asset requirements, you can define the `media` property directly. This is done by defining a widget property that returns an instance of `forms.Media`. The constructor for `forms.Media` accepts `css` and `js` keyword arguments in the same format as that used in a static media definition.

For example, the static definition for our `Calendar Widget` could also be defined in a dynamic fashion:

```
class CalendarWidget(forms.TextInput):
    def _media(self):
        return forms.Media(css={'all': ('pretty.css',)},
                           js=('animations.js', 'actions.js'))
    media = property(_media)
```

See the section on *Media objects* for more details on how to construct return values for dynamic media properties.

### Paths in asset definitions

Paths used to specify assets can be either relative or absolute. If a path starts with `/`, `http://` or `https://`, it will be interpreted as an absolute path, and left as-is. All other paths will be prepended with the value of the appropriate prefix. If the `django.contrib.staticfiles` app is installed, it will be used to serve assets.

Whether or not you use `django.contrib.staticfiles`, the `STATIC_URL` and `STATIC_ROOT` settings are required to render a complete web page.

To find the appropriate prefix to use, Django will check if the `STATIC_URL` setting is not `None` and automatically fall back to using `MEDIA_URL`. For example, if the `MEDIA_URL` for your site was `'http://uploads.example.com/'` and `STATIC_URL` was `None`:

```
>>> from django import forms
>>> class CalendarWidget(forms.TextInput):
...     class Media:
...         css = {
...             'all': ('/css/pretty.css',),
...         }
...         js = ('animations.js', 'http://othersite.com/actions.js')

>>> w = CalendarWidget()
>>> print(w.media)
<link href="/css/pretty.css" type="text/css" media="all" rel="stylesheet" />
<script type="text/javascript" src="http://uploads.example.com/animations.js"></script>
↪script>
<script type="text/javascript" src="http://othersite.com/actions.js"></script>
```

But if `STATIC_URL` is `'http://static.example.com/'`:

```
>>> w = CalendarWidget()
>>> print(w.media)
<link href="/css/pretty.css" type="text/css" media="all" rel="stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://othersite.com/actions.js"></script>
```

Or if `staticfiles` is configured using the `~django.contrib.staticfiles.ManifestStaticFilesStorage`:

```
>>> w = CalendarWidget()
>>> print(w.media)
<link href="/css/pretty.css" type="text/css" media="all" rel="stylesheet" />
<script type="text/javascript" src="https://static.example.com/animations.
↪27e20196a850.js"></script>
<script type="text/javascript" src="http://othersite.com/actions.js"></script>
```

Older versions didn't serve assets using `django.contrib.staticfiles`.

## Media objects

When you interrogate the `media` attribute of a widget or form, the value that is returned is a `forms.Media` object. As we have already seen, the string representation of a `Media` object is the HTML required to include the relevant files in the `<head>` block of your HTML page.

However, `Media` objects have some other interesting properties.

## Subsets of assets

If you only want files of a particular type, you can use the subscript operator to filter out a medium of interest. For example:

```
>>> w = CalendarWidget()
>>> print(w.media)
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>

>>> print(w.media['css'])
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
```

When you use the subscript operator, the value that is returned is a new `Media` object – but one that only contains the media of interest.

### Combining Media objects

Media objects can also be added together. When two `Media` objects are added, the resulting `Media` object contains the union of the assets specified by both:

```
>>> from django import forms
>>> class CalendarWidget(forms.TextInput):
...     class Media:
...         css = {
...             'all': ('pretty.css',)
...         }
...         js = ('animations.js', 'actions.js')

>>> class OtherWidget(forms.TextInput):
...     class Media:
...         js = ('whizbang.js',)

>>> w1 = CalendarWidget()
>>> w2 = OtherWidget()
>>> print(w1.media + w2.media)
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>
<script type="text/javascript" src="http://static.example.com/whizbang.js"></script>
```

### Media on Forms

Widgets aren't the only objects that can have media definitions – forms can also define media. The rules for media definitions on forms are the same as the rules for widgets: declarations can be static or dynamic; path and inheritance rules for those declarations are exactly the same.

Regardless of whether you define a media declaration, *all* Form objects have a `media` property. The default value for this property is the result of adding the media definitions for all widgets that are part of the form:

```
>>> from django import forms
>>> class ContactForm(forms.Form):
...     date = DateField(widget=CalendarWidget)
...     name = CharField(max_length=40, widget=OtherWidget)

>>> f = ContactForm()
```

```
>>> f.media
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>
<script type="text/javascript" src="http://static.example.com/whizbang.js"></script>
```

If you want to associate additional assets with a form – for example, CSS for form layout – simply add a Media declaration to the form:

```
>>> class ContactForm(forms.Form):
...     date = DateField(widget=CalendarWidget)
...     name = CharField(max_length=40, widget=OtherWidget)
...
...     class Media:
...         css = {
...             'all': ('layout.css',)
...         }
...
>>> f = ContactForm()
>>> f.media
<link href="http://static.example.com/pretty.css" type="text/css" media="all" rel=
↪"stylesheet" />
<link href="http://static.example.com/layout.css" type="text/css" media="all" rel=
↪"stylesheet" />
<script type="text/javascript" src="http://static.example.com/animations.js"></script>
<script type="text/javascript" src="http://static.example.com/actions.js"></script>
<script type="text/javascript" src="http://static.example.com/whizbang.js"></script>
```

*The Forms Reference* Covers the full API reference, including form fields, form widgets, and form and field validation.

## 3.5 Templates

Being a web framework, Django needs a convenient way to generate HTML dynamically. The most common approach relies on templates. A template contains the static parts of the desired HTML output as well as some special syntax describing how dynamic content will be inserted. For a hands-on example of creating HTML pages with templates, see *Tutorial 3*.

A Django project can be configured with one or several template engines (or even zero if you don't use templates). Django ships built-in backends for its own template system, creatively called the Django template language (DTL), and for the popular alternative *Jinja2*. Backends for other template languages may be available from third-parties.

Django defines a standard API for loading and rendering templates regardless of the backend. Loading consists of finding the template for a given identifier and preprocessing it, usually compiling it to an in-memory representation. Rendering means interpolating the template with context data and returning the resulting string.

The *Django template language* is Django's own template system. Until Django 1.8 it was the only built-in option available. It's a good template library even though it's fairly opinionated and sports a few idiosyncrasies. If you don't have a pressing reason to choose another backend, you should use the DTL, especially if you're writing a pluggable application and you intend to distribute templates. Django's contrib apps that include templates, like *django.contrib.admin*, use the DTL.

For historical reasons, both the generic support for template engines and the implementation of the Django template language live in the `django.template` namespace.

### 3.5.1 Support for template engines

#### Configuration

Templates engines are configured with the `TEMPLATES` setting. It's a list of configurations, one for each engine. The default value is empty. The `settings.py` generated by the `startproject` command defines a more useful value:

```
TEMPLATES = [
    {
        'BACKEND': 'django.template.backends.django.DjangoTemplates',
        'DIRS': [],
        'APP_DIRS': True,
        'OPTIONS': {
            # ... some options here ...
        },
    },
]
```

`BACKEND` is a dotted Python path to a template engine class implementing Django's template backend API. The built-in backends are `django.template.backends.django.DjangoTemplates` and `django.template.backends.jinja2.Jinja2`.

Since most engines load templates from files, the top-level configuration for each engine contains two common settings:

- `DIRS` defines a list of directories where the engine should look for template source files, in search order.
- `APP_DIRS` tells whether the engine should look for templates inside installed applications. Each backend defines a conventional name for the subdirectory inside applications where its templates should be stored.

While uncommon, it's possible to configure several instances of the same backend with different options. In that case you should define a unique `NAME` for each engine.

`OPTIONS` contains backend-specific settings.

#### Usage

The `django.template.loader` module defines two functions to load templates.

**get\_template** (*template\_name*, *using=None*)

This function loads the template with the given name and returns a `Template` object.

The exact type of the return value depends on the backend that loaded the template. Each backend has its own `Template` class.

`get_template()` tries each template engine in order until one succeeds. If the template cannot be found, it raises `TemplateDoesNotExist`. If the template is found but contains invalid syntax, it raises `TemplateSyntaxError`.

How templates are searched and loaded depends on each engine's backend and configuration.

If you want to restrict the search to a particular template engine, pass the engine's `NAME` in the `using` argument.

**select\_template** (*template\_name\_list*, *using=None*)

`select_template()` is just like `get_template()`, except it takes a list of template names. It tries each name in order and returns the first template that exists.

If loading a template fails, the following two exceptions, defined in `django.template`, may be raised:

**exception `TemplateDoesNotExist`** (*msg*, *tried=None*, *backend=None*, *chain=None*)

This exception is raised when a template cannot be found. It accepts the following optional arguments for populating the *template postmortem* on the debug page:

**backend** The template backend instance from which the exception originated.

**tried** A list of sources that were tried when finding the template. This is formatted as a list of tuples containing (*origin*, *status*), where *origin* is an *origin-like* object and *status* is a string with the reason the template wasn't found.

**chain** A list of intermediate `TemplateDoesNotExist` exceptions raised when trying to load a template. This is used by functions, such as `get_template()`, that try to load a given template from multiple engines.

The `backend`, `tried`, and `chain` arguments were added.

**exception `TemplateSyntaxError`** (*msg*)

This exception is raised when a template was found but contains errors.

Template objects returned by `get_template()` and `select_template()` must provide a `render()` method with the following signature:

Template.**render** (*context=None*, *request=None*)

Renders this template with a given context.

If `context` is provided, it must be a `dict`. If it isn't provided, the engine will render the template with an empty context.

If `request` is provided, it must be an `HttpRequest`. Then the engine must make it, as well as the CSRF token, available in the template. How this is achieved is up to each backend.

Here's an example of the search algorithm. For this example the `TEMPLATES` setting is:

```
TEMPLATES = [
    {
        'BACKEND': 'django.template.backends.django.DjangoTemplates',
        'DIRS': [
            '/home/html/example.com',
            '/home/html/default',
        ],
    },
    {
        'BACKEND': 'django.template.backends.jinja2.Jinja2',
        'DIRS': [
            '/home/html/jinja2',
        ],
    },
]
```

If you call `get_template('story_detail.html')`, here are the files Django will look for, in order:

- `/home/html/example.com/story_detail.html` ('django' engine)
- `/home/html/default/story_detail.html` ('django' engine)
- `/home/html/jinja2/story_detail.html` ('jinja2' engine)

If you call `select_template(['story_253_detail.html', 'story_detail.html'])`, here's what Django will look for:

- `/home/html/example.com/story_253_detail.html ('django' engine)`
- `/home/html/default/story_253_detail.html ('django' engine)`
- `/home/html/jinja2/story_253_detail.html ('jinja2' engine)`
- `/home/html/example.com/story_detail.html ('django' engine)`
- `/home/html/default/story_detail.html ('django' engine)`
- `/home/html/jinja2/story_detail.html ('jinja2' engine)`

When Django finds a template that exists, it stops looking.

---

### Tip

You can use `select_template()` for flexible template loading. For example, if you've written a news story and want some stories to have custom templates, use something like `select_template(['story_%s_detail.html' % story.id, 'story_detail.html'])`. That'll allow you to use a custom template for an individual story, with a fallback template for stories that don't have custom templates.

It's possible – and preferable – to organize templates in subdirectories inside each directory containing templates. The convention is to make a subdirectory for each Django app, with subdirectories within those subdirectories as needed.

Do this for your own sanity. Storing all templates in the root level of a single directory gets messy.

To load a template that's within a subdirectory, just use a slash, like so:

```
get_template('news/story_detail.html')
```

Using the same `TEMPLATES` option as above, this will attempt to load the following templates:

- `/home/html/example.com/news/story_detail.html ('django' engine)`
- `/home/html/default/news/story_detail.html ('django' engine)`
- `/home/html/jinja2/news/story_detail.html ('jinja2' engine)`

In addition, to cut down on the repetitive nature of loading and rendering templates, Django provides a shortcut function which automates the process.

**render\_to\_string** (*template\_name*, *context=None*, *request=None*, *using=None*)

`render_to_string()` loads a template like `get_template()` and calls its `render()` method immediately. It takes the following arguments.

**template\_name** The name of the template to load and render. If it's a list of template names, Django uses `select_template()` instead of `get_template()` to find the template.

**context** A `dict` to be used as the template's context for rendering.

**request** An optional `HttpRequest` that will be available during the template's rendering process.

**using** An optional template engine `NAME`. The search for the template will be restricted to that engine.

Usage example:

```
from django.template.loader import render_to_string
rendered = render_to_string('my_template.html', {'foo': 'bar'})
```

See also the `render()` shortcut which calls `render_to_string()` and feeds the result into an `HttpResponse` suitable for returning from a view.

Finally, you can use configured engines directly:

### engines

Template engines are available in `django.template.engines`:

```
from django.template import engines

django_engine = engines['django']
template = django_engine.from_string("Hello {{ name }}!")
```

The lookup key — 'django' in this example — is the engine's *NAME*.

## Built-in backends

### class DjangoTemplates

Set *BACKEND* to `'django.template.backends.django.DjangoTemplates'` to configure a Django template engine.

When *APP\_DIRS* is `True`, `DjangoTemplates` engines look for templates in the `templates` subdirectory of installed applications. This generic name was kept for backwards-compatibility.

`DjangoTemplates` engines accept the following *OPTIONS*:

- `'autoescape'`: a boolean that controls whether HTML autoescaping is enabled.

It defaults to `True`.

**Warning:** Only set it to `False` if you're rendering non-HTML templates!

The `autoescape` option was added.

- `'context_processors'`: a list of dotted Python paths to callables that are used to populate the context when a template is rendered with a request. These callables take a request object as their argument and return a `dict` of items to be merged into the context.

It defaults to an empty list.

See *RequestContext* for more information.

- `'debug'`: a boolean that turns on/off template debug mode. If it is `True`, the fancy error page will display a detailed report for any exception raised during template rendering. This report contains the relevant snippet of the template with the appropriate line highlighted.

It defaults to the value of the *DEBUG* setting.

- `'loaders'`: a list of dotted Python paths to template loader classes. Each `Loader` class knows how to import templates from a particular source. Optionally, a tuple can be used instead of a string. The first item in the tuple should be the `Loader` class name, and subsequent items are passed to the `Loader` during initialization.

The default depends on the values of *DIRS* and *APP\_DIRS*.

See *Loader types* for details.

- `'string_if_invalid'`: the output, as a string, that the template system should use for invalid (e.g. misspelled) variables.

It defaults to an empty string.

See *How invalid variables are handled* for details.

- 'file\_charset': the charset used to read template files on disk.

It defaults to the value of `FILE_CHARSET`.

- 'libraries': A dictionary of labels and dotted Python paths of template tag modules to register with the template engine. This can be used to add new libraries or provide alternate labels for existing ones. For example:

```
OPTIONS={
    'libraries': {
        'myapp_tags': 'path.to.myapp.tags',
        'admin.urls': 'django.contrib.admin.templatetags.admin_urls',
    },
}
```

Libraries can be loaded by passing the corresponding dictionary key to the `{% load %}` tag.

- 'builtins': A list of dotted Python paths of template tag modules to add to *built-ins*. For example:

```
OPTIONS={
    'builtins': ['myapp.builtins'],
}
```

Tags and filters from built-in libraries can be used without first calling the `{% load %}` tag.

The `libraries` and `builtins` arguments were added.

## class Jinja2

Requires `Jinja2` to be installed:

```
$ pip install Jinja2
```

Set `BACKEND` to `'django.template.backends.jinja2.Jinja2'` to configure a `Jinja2` engine.

When `APP_DIRS` is `True`, `Jinja2` engines look for templates in the `jinja2` subdirectory of installed applications.

The most important entry in `OPTIONS` is `'environment'`. It's a dotted Python path to a callable returning a `Jinja2` environment. It defaults to `'jinja2.Environment'`. Django invokes that callable and passes other options as keyword arguments. Furthermore, Django adds defaults that differ from `Jinja2`'s for a few options:

- 'autoescape': `True`
- 'loader': a loader configured for `DIRS` and `APP_DIRS`
- 'auto\_reload': `settings.DEBUG`
- 'undefined': `DebugUndefined` if `settings.DEBUG` else `Undefined`

The default configuration is purposefully kept to a minimum. If a template is rendered with a request (e.g. when using `render()`), the `Jinja2` backend adds the globals `request`, `csrf_input`, and `csrf_token` to the context. Apart from that, this backend doesn't create a Django-flavored environment. It doesn't know about Django context processors, filters, and tags. In order to use Django-specific APIs, you must configure them into the environment.

For example, you can create `myproject/jinja2.py` with this content:

```
from __future__ import absolute_import # Python 2 only

from django.contrib.staticfiles.storage import staticfiles_storage
from django.urls import reverse

from jinja2 import Environment
```

```
def environment(**options):
    env = Environment(**options)
    env.globals.update({
        'static': staticfiles_storage.url,
        'url': reverse,
    })
    return env
```

and set the 'environment' option to 'myproject.jinja2.environment'.

Then you could use the following constructs in Jinja2 templates:

```

<a href="{{ url('admin:index') }}">Administration</a>
```

The concepts of tags and filters exist both in the Django template language and in Jinja2 but they're used differently. Since Jinja2 supports passing arguments to callables in templates, many features that require a template tag or filter in Django templates can be achieved simply by calling a function in Jinja2 templates, as shown in the example above. Jinja2's global namespace removes the need for template context processors. The Django template language doesn't have an equivalent of Jinja2 tests.

## Custom backends

Here's how to implement a custom template backend in order to use another template system. A template backend is a class that inherits `django.template.backends.base.BaseEngine`. It must implement `get_template()` and optionally `from_string()`. Here's an example for a fictional foobar template library:

```
from django.template import TemplateDoesNotExist, TemplateSyntaxError
from django.template.backends.base import BaseEngine
from django.template.backends.utils import csrf_input_lazy, csrf_token_lazy

import foobar

class FooBar(BaseEngine):

    # Name of the subdirectory containing the templates for this engine
    # inside an installed application.
    app_dirname = 'foobar'

    def __init__(self, params):
        params = params.copy()
        options = params.pop('OPTIONS').copy()
        super(FooBar, self).__init__(params)

        self.engine = foobar.Engine(**options)

    def from_string(self, template_code):
        try:
            return Template(self.engine.from_string(template_code))
        except foobar.TemplateCompilationFailed as exc:
            raise TemplateSyntaxError(exc.args)

    def get_template(self, template_name):
```

```
    try:
        return Template(self.engine.get_template(template_name))
    except foobar.TemplateNotFound as exc:
        raise TemplateDoesNotExist(exc.args, backend=self)
    except foobar.TemplateCompilationFailed as exc:
        raise TemplateSyntaxError(exc.args)

class Template(object):

    def __init__(self, template):
        self.template = template

    def render(self, context=None, request=None):
        if context is None:
            context = {}
        if request is not None:
            context['request'] = request
            context['csrf_input'] = csrf_input_lazy(request)
            context['csrf_token'] = csrf_token_lazy(request)
        return self.template.render(context)
```

See [DEP 182](#) for more information.

## Debug integration for custom engines

Debug page integration for non-Django template engines was added.

The Django debug page has hooks to provide detailed information when a template error arises. Custom template engines can use these hooks to enhance the traceback information that appears to users. The following hooks are available:

### Template postmortem

The postmortem appears when `TemplateDoesNotExist` is raised. It lists the template engines and loaders that were used when trying to find a given template. For example, if two Django engines are configured, the postmortem will appear like:

#### Template-loader postmortem

Django tried loading these templates, in this order:

Using engine `django`:

- `django.template.loaders.filesystem.Loader: /path/to/templates/xnotexists.html (Source does not exist)`
- `django.template.loaders.filesystem.Loader: /path/to/templates2/xnotexists.html (Source does not exist)`
- `django.template.loaders.app_directories.Loader: /path/to/app1/templates/xnotexists.html (Source does not exist)`

Using engine `django2`:

- `django.template.loaders.filesystem.Loader: /path/to/django2/xnotexists.html (Source does not exist)`

Custom engines can populate the postmortem by passing the `backend` and `tried` arguments when raising `TemplateDoesNotExist`. Backends that use the postmortem *should specify an origin* on the template object.

## Contextual line information

If an error happens during template parsing or rendering, Django can display the line the error happened on. For example:

### Error during template rendering

In template `/path/to/template.html`, error at line 4

#### Invalid block tag: 'syntax'

1	some
2	lines
3	before
4	Hello {% syntax error %} {{ world }}
5	some
6	lines
7	after
8	

Custom engines can populate this information by setting a `template_debug` attribute on exceptions raised during parsing and rendering. This attribute is a `dict` with the following values:

- `'name'`: The name of the template in which the exception occurred.
- `'message'`: The exception message.
- `'source_lines'`: The lines before, after, and including the line the exception occurred on. This is for context, so it shouldn't contain more than 20 lines or so.
- `'line'`: The line number on which the exception occurred.
- `'before'`: The content on the error line before the token that raised the error.
- `'during'`: The token that raised the error.
- `'after'`: The content on the error line after the token that raised the error.
- `'total'`: The number of lines in `source_lines`.
- `'top'`: The line number where `source_lines` starts.
- `'bottom'`: The line number where `source_lines` ends.

Given the above template error, `template_debug` would look like:

```
{
  'name': '/path/to/template.html',
  'message': "Invalid block tag: 'syntax'",
  'source_lines': [
    (1, 'some\n'),
    (2, 'lines\n'),
    (3, 'before\n'),
    (4, 'Hello {% syntax error %} {{ world }}\n'),
    (5, 'some\n'),
    (6, 'lines\n'),
    (7, 'after\n'),
    (8, ''),
  ],
  'line': 4,
  'before': 'Hello ',
```

```
'during': '{% syntax error %}',
'after': '{{ world }}\n',
'total': 9,
'bottom': 9,
'top': 1,
}
```

## Origin API and 3rd-party integration

Django templates have an *Origin* object available through the `template.origin` attribute. This enables debug information to be displayed in the *template postmortem*, as well as in 3rd-party libraries, like the [Django Debug Toolbar](#).

Custom engines can provide their own `template.origin` information by creating an object that specifies the following attributes:

- `'name'`: The full path to the template.
- `'template_name'`: The relative path to the template as passed into the the template loading methods.
- `'loader_name'`: An optional string identifying the function or class used to load the template, e.g. `django.template.loaders.filesystem.Loader`.

## 3.5.2 The Django template language

### Syntax

---

#### About this section

This is an overview of the Django template language's syntax. For details see the [language syntax reference](#).

---

A Django template is simply a text document or a Python string marked-up using the Django template language. Some constructs are recognized and interpreted by the template engine. The main ones are variables and tags.

A template is rendered with a context. Rendering replaces variables with their values, which are looked up in the context, and executes tags. Everything else is output as is.

The syntax of the Django template language involves four constructs.

### Variables

A variable outputs a value from the context, which is a dict-like object mapping keys to values.

Variables are surrounded by `{{` and `}}` like this:

```
My first name is {{ first_name }}. My last name is {{ last_name }}.
```

With a context of `{'first_name': 'John', 'last_name': 'Doe'}`, this template renders to:

```
My first name is John. My last name is Doe.
```

Dictionary lookup, attribute lookup and list-index lookups are implemented with a dot notation:

```

{{ my_dict.key }}
{{ my_object.attribute }}
{{ my_list.0 }}

```

If a variable resolves to a callable, the template system will call it with no arguments and use its result instead of the callable.

## Tags

Tags provide arbitrary logic in the rendering process.

This definition is deliberately vague. For example, a tag can output content, serve as a control structure e.g. an “if” statement or a “for” loop, grab content from a database, or even enable access to other template tags.

Tags are surrounded by `{% and %}` like this:

```
{% csrf_token %}
```

Most tags accept arguments:

```
{% cycle 'odd' 'even' %}
```

Some tags require beginning and ending tags:

```
{% if user.is_authenticated %}Hello, {{ user.username }}.{% endif %}
```

A *reference of built-in tags* is available as well as *instructions for writing custom tags*.

## Filters

Filters transform the values of variables and tag arguments.

They look like this:

```
{{ django|title }}
```

With a context of `{'django': 'the web framework for perfectionists with deadlines'}`, this template renders to:

```
The Web Framework For Perfectionists With Deadlines
```

Some filters take an argument:

```
{{ my_date|date:"Y-m-d" }}
```

A *reference of built-in filters* is available as well as *instructions for writing custom filters*.

## Comments

Comments look like this:

```
{# this won't be rendered #}
```

A `{% comment %}` tag provides multi-line comments.

## Components

---

### About this section

This is an overview of the Django template language's APIs. For details see the *API reference*.

---

### Engine

`django.template.Engine` encapsulates an instance of the Django template system. The main reason for instantiating an `Engine` directly is to use the Django template language outside of a Django project.

`django.template.backends.django.DjangoTemplates` is a thin wrapper adapting `django.template.Engine` to Django's template backend API.

### Template

`django.template.Template` represents a compiled template. Templates are obtained with `Engine.get_template()` or `Engine.from_string()`

Likewise `django.template.backends.django.Template` is a thin wrapper adapting `django.template.Template` to the common template API.

### Context

`django.template.Context` holds some metadata in addition to the context data. It is passed to `Template.render()` for rendering a template.

`django.template.RequestContext` is a subclass of `Context` that stores the current `HttpRequest` and runs template context processors.

The common API doesn't have an equivalent concept. Context data is passed in a plain `dict` and the current `HttpRequest` is passed separately if needed.

### Loaders

Template loaders are responsible for locating templates, loading them, and returning `Template` objects.

Django provides several *built-in template loaders* and supports *custom template loaders*.

### Context processors

Context processors are functions that receive the current `HttpRequest` as an argument and return a `dict` of data to be added to the rendering context.

Their main use is to add common data shared by all templates to the context without repeating code in every view.

Django provides many *built-in context processors*. Implementing a custom context processor is as simple as defining a function.

## 3.6 Class-based views

A view is a callable which takes a request and returns a response. This can be more than just a function, and Django provides an example of some classes which can be used as views. These allow you to structure your views and reuse code by harnessing inheritance and mixins. There are also some generic views for simple tasks which we'll get to later, but you may want to design your own structure of reusable views which suits your use case. For full details, see the *class-based views reference documentation*.

### 3.6.1 Introduction to class-based views

Class-based views provide an alternative way to implement views as Python objects instead of functions. They do not replace function-based views, but have certain differences and advantages when compared to function-based views:

- Organization of code related to specific HTTP methods (GET, POST, etc.) can be addressed by separate methods instead of conditional branching.
- Object oriented techniques such as mixins (multiple inheritance) can be used to factor code into reusable components.

#### The relationship and history of generic views, class-based views, and class-based generic views

In the beginning there was only the view function contract, Django passed your function an `HttpRequest` and expected back an `HttpResponse`. This was the extent of what Django provided.

Early on it was recognized that there were common idioms and patterns found in view development. Function-based generic views were introduced to abstract these patterns and ease view development for the common cases.

The problem with function-based generic views is that while they covered the simple cases well, there was no way to extend or customize them beyond some simple configuration options, limiting their usefulness in many real-world applications.

Class-based generic views were created with the same objective as function-based generic views, to make view development easier. However, the way the solution is implemented, through the use of mixins, provides a toolkit that results in class-based generic views being more extensible and flexible than their function-based counterparts.

If you have tried function based generic views in the past and found them lacking, you should not think of class-based generic views as simply a class-based equivalent, but rather as a fresh approach to solving the original problems that generic views were meant to solve.

The toolkit of base classes and mixins that Django uses to build class-based generic views are built for maximum flexibility, and as such have many hooks in the form of default method implementations and attributes that you are unlikely to be concerned with in the simplest use cases. For example, instead of limiting you to a class-based attribute for `form_class`, the implementation uses a `get_form` method, which calls a `get_form_class` method, which in its default implementation just returns the `form_class` attribute of the class. This gives you several options for specifying what form to use, from a simple attribute, to a fully dynamic, callable hook. These options seem to add hollow complexity for simple situations, but without them, more advanced designs would be limited.

#### Using class-based views

At its core, a class-based view allows you to respond to different HTTP request methods with different class instance methods, instead of with conditionally branching code inside a single view function.

So where the code to handle HTTP GET in a view function would look something like:

```
from django.http import HttpResponseRedirect

def my_view(request):
    if request.method == 'GET':
        # <view logic>
        return HttpResponseRedirect('result')
```

In a class-based view, this would become:

```
from django.http import HttpResponseRedirect
from django.views import View

class MyView(View):
    def get(self, request):
        # <view logic>
        return HttpResponseRedirect('result')
```

Because Django's URL resolver expects to send the request and associated arguments to a callable function, not a class, class-based views have an `as_view()` class method which returns a function that can be called when a request arrives for a URL matching the associated pattern. The function creates an instance of the class and calls its `dispatch()` method. `dispatch` looks at the request to determine whether it is a GET, POST, etc, and relays the request to a matching method if one is defined, or raises `HttpResponseNotAllowed` if not:

```
# urls.py
from django.conf.urls import url
from myapp.views import MyView

urlpatterns = [
    url(r'^about/$', MyView.as_view()),
]
```

It is worth noting that what your method returns is identical to what you return from a function-based view, namely some form of `HttpResponse`. This means that `http shortcuts` or `TemplateResponse` objects are valid to use inside a class-based view.

While a minimal class-based view does not require any class attributes to perform its job, class attributes are useful in many class-based designs, and there are two ways to configure or set class attributes.

The first is the standard Python way of subclassing and overriding attributes and methods in the subclass. So that if your parent class had an attribute `greeting` like this:

```
from django.http import HttpResponseRedirect
from django.views import View

class GreetingView(View):
    greeting = "Good Day"

    def get(self, request):
        return HttpResponseRedirect(self.greeting)
```

You can override that in a subclass:

```
class MorningGreetingView(GreetingView):
    greeting = "Morning to ya"
```

Another option is to configure class attributes as keyword arguments to the `as_view()` call in the URLconf:

```
urlpatterns = [
    url(r'^about/$', GreetingView.as_view(greeting="G'day")),
]
```

**Note:** While your class is instantiated for each request dispatched to it, class attributes set through the `as_view()` entry point are configured only once at the time your URLs are imported.

## Using mixins

Mixins are a form of multiple inheritance where behaviors and attributes of multiple parent classes can be combined.

For example, in the generic class-based views there is a mixin called `TemplateResponseMixin` whose primary purpose is to define the method `render_to_response()`. When combined with the behavior of the `View` base class, the result is a `TemplateView` class that will dispatch requests to the appropriate matching methods (a behavior defined in the `View` base class), and that has a `render_to_response()` method that uses a `template_name` attribute to return a `TemplateResponse` object (a behavior defined in the `TemplateResponseMixin`).

Mixins are an excellent way of reusing code across multiple classes, but they come with some cost. The more your code is scattered among mixins, the harder it will be to read a child class and know what exactly it is doing, and the harder it will be to know which methods from which mixins to override if you are subclassing something that has a deep inheritance tree.

Note also that you can only inherit from one generic view - that is, only one parent class may inherit from `View` and the rest (if any) should be mixins. Trying to inherit from more than one class that inherits from `View` - for example, trying to use a form at the top of a list and combining `ProcessFormView` and `ListView` - won't work as expected.

## Handling forms with class-based views

A basic function-based view that handles forms may look something like this:

```
from django.http import HttpResponseRedirect
from django.shortcuts import render

from .forms import MyForm

def myview(request):
    if request.method == "POST":
        form = MyForm(request.POST)
        if form.is_valid():
            # <process form cleaned data>
            return HttpResponseRedirect('/success/')
    else:
        form = MyForm(initial={'key': 'value'})

    return render(request, 'form_template.html', {'form': form})
```

A similar class-based view might look like:

```
from django.http import HttpResponseRedirect
from django.shortcuts import render
from django.views import View

from .forms import MyForm
```

```
class MyFormView(View):
    form_class = MyForm
    initial = {'key': 'value'}
    template_name = 'form_template.html'

    def get(self, request, *args, **kwargs):
        form = self.form_class(initial=self.initial)
        return render(request, self.template_name, {'form': form})

    def post(self, request, *args, **kwargs):
        form = self.form_class(request.POST)
        if form.is_valid():
            # <process form cleaned data>
            return HttpResponseRedirect('/success/')

        return render(request, self.template_name, {'form': form})
```

This is a very simple case, but you can see that you would then have the option of customizing this view by overriding any of the class attributes, e.g. `form_class`, via URLconf configuration, or subclassing and overriding one or more of the methods (or both!).

### Decorating class-based views

The extension of class-based views isn't limited to using mixins. You can also use decorators. Since class-based views aren't functions, decorating them works differently depending on if you're using `as_view()` or creating a subclass.

### Decorating in URLconf

The simplest way of decorating class-based views is to decorate the result of the `as_view()` method. The easiest place to do this is in the URLconf where you deploy your view:

```
from django.contrib.auth.decorators import login_required, permission_required
from django.views.generic import TemplateView

from .views import VoteView

urlpatterns = [
    url(r'^about/$', login_required(TemplateView.as_view(template_name="secret.html
↪"))),
    url(r'^vote/$', permission_required('polls.can_vote')(VoteView.as_view())),
]
```

This approach applies the decorator on a per-instance basis. If you want every instance of a view to be decorated, you need to take a different approach.

### Decorating the class

To decorate every instance of a class-based view, you need to decorate the class definition itself. To do this you apply the decorator to the `dispatch()` method of the class.

A method on a class isn't quite the same as a standalone function, so you can't just apply a function decorator to the method – you need to transform it into a method decorator first. The `method_decorator` decorator transforms a function decorator into a method decorator so that it can be used on an instance method. For example:

```

from django.contrib.auth.decorators import login_required
from django.utils.decorators import method_decorator
from django.views.generic import TemplateView

class ProtectedView(TemplateView):
    template_name = 'secret.html'

    @method_decorator(login_required)
    def dispatch(self, *args, **kwargs):
        return super(ProtectedView, self).dispatch(*args, **kwargs)

```

Or, more succinctly, you can decorate the class instead and pass the name of the method to be decorated as the keyword argument name:

```

@method_decorator(login_required, name='dispatch')
class ProtectedView(TemplateView):
    template_name = 'secret.html'

```

If you have a set of common decorators used in several places, you can define a list or tuple of decorators and use this instead of invoking `method_decorator()` multiple times. These two classes are equivalent:

```

decorators = [never_cache, login_required]

@method_decorator(decorators, name='dispatch')
class ProtectedView(TemplateView):
    template_name = 'secret.html'

@method_decorator(never_cache, name='dispatch')
@method_decorator(login_required, name='dispatch')
class ProtectedView(TemplateView):
    template_name = 'secret.html'

```

The decorators will process a request in the order they are passed to the decorator. In the example, `never_cache()` will process the request before `login_required()`.

The ability to use `method_decorator()` on a class and the ability for it to accept a list or tuple of decorators were added.

In this example, every instance of `ProtectedView` will have login protection.

---

**Note:** `method_decorator` passes `*args` and `**kwargs` as parameters to the decorated method on the class. If your method does not accept a compatible set of parameters it will raise a `TypeError` exception.

---

## 3.6.2 Built-in class-based generic views

Writing Web applications can be monotonous, because we repeat certain patterns again and again. Django tries to take away some of that monotony at the model and template layers, but Web developers also experience this boredom at the view level.

Django's *generic views* were developed to ease that pain. They take certain common idioms and patterns found in view development and abstract them so that you can quickly write common views of data without having to write too much code.

We can recognize certain common tasks, like displaying a list of objects, and write code that displays a list of *any* object. Then the model in question can be passed as an extra argument to the `URLconf`.

Django ships with generic views to do the following:

- Display list and detail pages for a single object. If we were creating an application to manage conferences then a `TalkListView` and a `RegisteredUserListView` would be examples of list views. A single talk page is an example of what we call a “detail” view.
- Present date-based objects in year/month/day archive pages, associated detail, and “latest” pages.
- Allow users to create, update, and delete objects – with or without authorization.

Taken together, these views provide easy interfaces to perform the most common tasks developers encounter.

## Extending generic views

There’s no question that using generic views can speed up development substantially. In most projects, however, there comes a moment when the generic views no longer suffice. Indeed, the most common question asked by new Django developers is how to make generic views handle a wider array of situations.

This is one of the reasons generic views were redesigned for the 1.3 release - previously, they were just view functions with a bewildering array of options; now, rather than passing in a large amount of configuration in the URLconf, the recommended way to extend generic views is to subclass them, and override their attributes or methods.

That said, generic views will have a limit. If you find you’re struggling to implement your view as a subclass of a generic view, then you may find it more effective to write just the code you need, using your own class-based or functional views.

More examples of generic views are available in some third party applications, or you could write your own as needed.

## Generic views of objects

`TemplateView` certainly is useful, but Django’s generic views really shine when it comes to presenting views of your database content. Because it’s such a common task, Django comes with a handful of built-in generic views that make generating list and detail views of objects incredibly easy.

Let’s start by looking at some examples of showing a list of objects or an individual object.

We’ll be using these models:

```
# models.py
from django.db import models

class Publisher(models.Model):
    name = models.CharField(max_length=30)
    address = models.CharField(max_length=50)
    city = models.CharField(max_length=60)
    state_province = models.CharField(max_length=30)
    country = models.CharField(max_length=50)
    website = models.URLField()

    class Meta:
        ordering = ["-name"]

    def __str__(self):
        # __unicode__ on Python 2
        return self.name

class Author(models.Model):
    salutation = models.CharField(max_length=10)
    name = models.CharField(max_length=200)
    email = models.EmailField()
```

```

headshot = models.ImageField(upload_to='author_headshots')

def __str__(self):
    return self.name

class Book(models.Model):
    title = models.CharField(max_length=100)
    authors = models.ManyToManyField('Author')
    publisher = models.ForeignKey(Publisher, on_delete=models.CASCADE)
    publication_date = models.DateField()

```

Now we need to define a view:

```

# views.py
from django.views.generic import ListView
from books.models import Publisher

class PublisherList(ListView):
    model = Publisher

```

Finally hook that view into your urls:

```

# urls.py
from django.conf.urls import url
from books.views import PublisherList

urlpatterns = [
    url(r'^publishers/$', PublisherList.as_view()),
]

```

That’s all the Python code we need to write. We still need to write a template, however. We could explicitly tell the view which template to use by adding a `template_name` attribute to the view, but in the absence of an explicit template Django will infer one from the object’s name. In this case, the inferred template will be `"books/publisher_list.html"` – the “books” part comes from the name of the app that defines the model, while the “publisher” bit is just the lowercased version of the model’s name.

---

**Note:** Thus, when (for example) the `APP_DIRS` option of a `DjangoTemplates` backend is set to `True` in `TEMPLATES`, a template location could be: `/path/to/project/books/templates/books/publisher_list.html`

---

This template will be rendered against a context containing a variable called `object_list` that contains all the publisher objects. A very simple template might look like the following:

```

{% extends "base.html" %}

{% block content %}
    <h2>Publishers</h2>
    <ul>
        {% for publisher in object_list %}
            <li>{{ publisher.name }}</li>
        {% endfor %}
    </ul>
{% endblock %}

```

That’s really all there is to it. All the cool features of generic views come from changing the attributes set on the generic view. The [generic views reference](#) documents all the generic views and their options in detail; the rest of this document will consider some of the common ways you might customize and extend generic views.

## Making “friendly” template contexts

You might have noticed that our sample publisher list template stores all the publishers in a variable named `object_list`. While this works just fine, it isn’t all that “friendly” to template authors: they have to “just know” that they’re dealing with publishers here.

Well, if you’re dealing with a model object, this is already done for you. When you are dealing with an object or queryset, Django is able to populate the context using the lower cased version of the model class’ name. This is provided in addition to the default `object_list` entry, but contains exactly the same data, i.e. `publisher_list`.

If this still isn’t a good match, you can manually set the name of the context variable. The `context_object_name` attribute on a generic view specifies the context variable to use:

```
# views.py
from django.views.generic import ListView
from books.models import Publisher

class PublisherList(ListView):
    model = Publisher
    context_object_name = 'my_favorite_publishers'
```

Providing a useful `context_object_name` is always a good idea. Your coworkers who design templates will thank you.

## Adding extra context

Often you simply need to present some extra information beyond that provided by the generic view. For example, think of showing a list of all the books on each publisher detail page. The `DetailView` generic view provides the publisher to the context, but how do we get additional information in that template?

The answer is to subclass `DetailView` and provide your own implementation of the `get_context_data` method. The default implementation simply adds the object being displayed to the template, but you can override it to send more:

```
from django.views.generic import DetailView
from books.models import Publisher, Book

class PublisherDetail(DetailView):

    model = Publisher

    def get_context_data(self, **kwargs):
        # Call the base implementation first to get a context
        context = super(PublisherDetail, self).get_context_data(**kwargs)
        # Add in a QuerySet of all the books
        context['book_list'] = Book.objects.all()
        return context
```

---

**Note:** Generally, `get_context_data` will merge the context data of all parent classes with those of the current class. To preserve this behavior in your own classes where you want to alter the context, you should be sure to call `get_context_data` on the super class. When no two classes try to define the same key, this will give the expected results. However if any class attempts to override a key after parent classes have set it (after the call to `super`), any children of that class will also need to explicitly set it after `super` if they want to be sure to override all parents. If you’re having trouble, review the method resolution order of your view.

Another consideration is that the context data from class-based generic views will override data provided by context processors; see `get_context_data()` for an example.

## Viewing subsets of objects

Now let’s take a closer look at the `model` argument we’ve been using all along. The `model` argument, which specifies the database model that the view will operate upon, is available on all the generic views that operate on a single object or a collection of objects. However, the `model` argument is not the only way to specify the objects that the view will operate upon – you can also specify the list of objects using the `queryset` argument:

```
from django.views.generic import DetailView
from books.models import Publisher

class PublisherDetail(DetailView):
    context_object_name = 'publisher'
    queryset = Publisher.objects.all()
```

Specifying `model = Publisher` is really just shorthand for saying `queryset = Publisher.objects.all()`. However, by using `queryset` to define a filtered list of objects you can be more specific about the objects that will be visible in the view (see *Making queries* for more information about `QuerySet` objects, and see the *class-based views reference* for the complete details).

To pick a simple example, we might want to order a list of books by publication date, with the most recent first:

```
from django.views.generic import ListView
from books.models import Book

class BookList(ListView):
    queryset = Book.objects.order_by('-publication_date')
    context_object_name = 'book_list'
```

That’s a pretty simple example, but it illustrates the idea nicely. Of course, you’ll usually want to do more than just reorder objects. If you want to present a list of books by a particular publisher, you can use the same technique:

```
from django.views.generic import ListView
from books.models import Book

class AcmeBookList(ListView):
    context_object_name = 'book_list'
    queryset = Book.objects.filter(publisher__name='ACME Publishing')
    template_name = 'books/acme_list.html'
```

Notice that along with a filtered `queryset`, we’re also using a custom template name. If we didn’t, the generic view would use the same template as the “vanilla” object list, which might not be what we want.

Also notice that this isn’t a very elegant way of doing publisher-specific books. If we want to add another publisher page, we’d need another handful of lines in the URLconf, and more than a few publishers would get unreasonable. We’ll deal with this problem in the next section.

---

**Note:** If you get a 404 when requesting `/books/acme/`, check to ensure you actually have a `Publisher` with the name ‘ACME Publishing’. Generic views have an `allow_empty` parameter for this case. See the *class-based-views reference* for more details.

---

## Dynamic filtering

Another common need is to filter down the objects given in a list page by some key in the URL. Earlier we hard-coded the publisher's name in the URLconf, but what if we wanted to write a view that displayed all the books by some arbitrary publisher?

Handily, the `ListView` has a `get_queryset()` method we can override. Previously, it has just been returning the value of the `queryset` attribute, but now we can add more logic.

The key part to making this work is that when class-based views are called, various useful things are stored on `self`; as well as the request (`self.request`) this includes the positional (`self.args`) and name-based (`self.kwargs`) arguments captured according to the URLconf.

Here, we have a URLconf with a single captured group:

```
# urls.py
from django.conf.urls import url
from books.views import PublisherBookList

urlpatterns = [
    url(r'^books/([\w-]+)/$', PublisherBookList.as_view()),
]
```

Next, we'll write the `PublisherBookList` view itself:

```
# views.py
from django.shortcuts import get_object_or_404
from django.views.generic import ListView
from books.models import Book, Publisher

class PublisherBookList(ListView):

    template_name = 'books/books_by_publisher.html'

    def get_queryset(self):
        self.publisher = get_object_or_404(Publisher, name=self.args[0])
        return Book.objects.filter(publisher=self.publisher)
```

As you can see, it's quite easy to add more logic to the queryset selection; if we wanted, we could use `self.request.user` to filter using the current user, or other more complex logic.

We can also add the publisher into the context at the same time, so we can use it in the template:

```
# ...

def get_context_data(self, **kwargs):
    # Call the base implementation first to get a context
    context = super(PublisherBookList, self).get_context_data(**kwargs)
    # Add in the publisher
    context['publisher'] = self.publisher
    return context
```

## Performing extra work

The last common pattern we'll look at involves doing some extra work before or after calling the generic view.

Imagine we had a `last_accessed` field on our `Author` model that we were using to keep track of the last time anybody looked at that author:

```
# models.py
from django.db import models

class Author(models.Model):
    salutation = models.CharField(max_length=10)
    name = models.CharField(max_length=200)
    email = models.EmailField()
    headshot = models.ImageField(upload_to='author_headshots')
    last_accessed = models.DateTimeField()
```

The generic `DetailView` class, of course, wouldn't know anything about this field, but once again we could easily write a custom view to keep that field updated.

First, we'd need to add an author detail bit in the `URLconf` to point to a custom view:

```
from django.conf.urls import url
from books.views import AuthorDetailView

urlpatterns = [
    #...
    url(r'^authors/(?P<pk>[0-9]+)/$', AuthorDetailView.as_view(), name='author-detail
↪'),
]
```

Then we'd write our new view – `get_object` is the method that retrieves the object – so we simply override it and wrap the call:

```
from django.views.generic import DetailView
from django.utils import timezone
from books.models import Author

class AuthorDetailView(DetailView):

    queryset = Author.objects.all()

    def get_object(self):
        # Call the superclass
        object = super(AuthorDetailView, self).get_object()
        # Record the last accessed date
        object.last_accessed = timezone.now()
        object.save()
        # Return the object
        return object
```

**Note:** The `URLconf` here uses the named group `pk` - this name is the default name that `DetailView` uses to find the value of the primary key used to filter the queryset.

If you want to call the group something else, you can set `pk_url_kwarg` on the view. More details can be found in the reference for [DetailView](#)

### 3.6.3 Form handling with class-based views

Form processing generally has 3 paths:

- Initial GET (blank or prepopulated form)

- POST with invalid data (typically redisplay form with errors)
- POST with valid data (process the data and typically redirect)

Implementing this yourself often results in a lot of repeated boilerplate code (see *Using a form in a view*). To help avoid this, Django provides a collection of generic class-based views for form processing.

## Basic forms

Given a simple contact form:

```
forms.py

from django import forms

class ContactForm(forms.Form):
    name = forms.CharField()
    message = forms.CharField(widget=forms.Textarea)

    def send_email(self):
        # send email using the self.cleaned_data dictionary
        pass
```

The view can be constructed using a `FormView`:

```
views.py

from myapp.forms import ContactForm
from django.views.generic.edit import FormView

class ContactView(FormView):
    template_name = 'contact.html'
    form_class = ContactForm
    success_url = '/thanks/'

    def form_valid(self, form):
        # This method is called when valid form data has been POSTed.
        # It should return an HttpResponseRedirect.
        form.send_email()
        return super(ContactView, self).form_valid(form)
```

Notes:

- `FormView` inherits `TemplateResponseMixin` so `template_name` can be used here.
- The default implementation for `form_valid()` simply redirects to the `success_url`.

## Model forms

Generic views really shine when working with models. These generic views will automatically create a `ModelForm`, so long as they can work out which model class to use:

- If the `model` attribute is given, that model class will be used.
- If `get_object()` returns an object, the class of that object will be used.
- If a `queryset` is given, the model for that queryset will be used.

Model form views provide a `form_valid()` implementation that saves the model automatically. You can override this if you have any special requirements; see below for examples.

You don't even need to provide a `success_url` for `CreateView` or `UpdateView` - they will use `get_absolute_url()` on the model object if available.

If you want to use a custom `ModelForm` (for instance to add extra validation) simply set `form_class` on your view.

---

**Note:** When specifying a custom form class, you must still specify the model, even though the `form_class` may be a `ModelForm`.

---

First we need to add `get_absolute_url()` to our `Author` class:

```
models.py

from django.urls import reverse
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=200)

    def get_absolute_url(self):
        return reverse('author-detail', kwargs={'pk': self.pk})
```

Then we can use `CreateView` and friends to do the actual work. Notice how we're just configuring the generic class-based views here; we don't have to write any logic ourselves:

```
views.py

from django.views.generic.edit import CreateView, UpdateView, DeleteView
from django.urls import reverse_lazy
from myapp.models import Author

class AuthorCreate(CreateView):
    model = Author
    fields = ['name']

class AuthorUpdate(UpdateView):
    model = Author
    fields = ['name']

class AuthorDelete(DeleteView):
    model = Author
    success_url = reverse_lazy('author-list')
```

---

**Note:** We have to use `reverse_lazy()` here, not just `reverse()` as the urls are not loaded when the file is imported.

---

The `fields` attribute works the same way as the `fields` attribute on the inner `Meta` class on `ModelForm`. Unless you define the form class in another way, the attribute is required and the view will raise an `ImproperlyConfigured` exception if it's not.

If you specify both the `fields` and `form_class` attributes, an `ImproperlyConfigured` exception will be raised.

Finally, we hook these new views into the URLconf:

```
urls.py

from django.conf.urls import url
from myapp.views import AuthorCreate, AuthorUpdate, AuthorDelete
```

```
urlpatterns = [  
    # ...  
    url(r'author/add/$', AuthorCreate.as_view(), name='author-add'),  
    url(r'author/(?P<pk>[0-9]+)/$', AuthorUpdate.as_view(), name='author-update'),  
    url(r'author/(?P<pk>[0-9]+)/delete/$', AuthorDelete.as_view(), name='author-delete'),  
]
```

---

**Note:** These views inherit `SingleObjectTemplateResponseMixin` which uses `template_name_suffix` to construct the `template_name` based on the model.

In this example:

- `CreateView` and `UpdateView` use `myapp/author_form.html`
- `DeleteView` uses `myapp/author_confirm_delete.html`

If you wish to have separate templates for `CreateView` and `UpdateView`, you can set either `template_name` or `template_name_suffix` on your view class.

---

## Models and `request.user`

To track the user that created an object using a `CreateView`, you can use a custom `ModelForm` to do this. First, add the foreign key relation to the model:

```
models.py
```

```
from django.contrib.auth.models import User  
from django.db import models  
  
class Author(models.Model):  
    name = models.CharField(max_length=200)  
    created_by = models.ForeignKey(User, on_delete=models.CASCADE)  
  
    # ...
```

In the view, ensure that you don't include `created_by` in the list of fields to edit, and override `form_valid()` to add the user:

```
views.py
```

```
from django.views.generic.edit import CreateView  
from myapp.models import Author  
  
class AuthorCreate(CreateView):  
    model = Author  
    fields = ['name']  
  
    def form_valid(self, form):  
        form.instance.created_by = self.request.user  
        return super(AuthorCreate, self).form_valid(form)
```

Note that you'll need to *decorate this view* using `login_required()`, or alternatively handle unauthorized users in the `form_valid()`.

## AJAX example

Here is a simple example showing how you might go about implementing a form that works for AJAX requests as well as ‘normal’ form POSTs:

```

from django.http import JsonResponse
from django.views.generic.edit import CreateView
from myapp.models import Author

class AjaxableResponseMixin(object):
    """
    Mixin to add AJAX support to a form.
    Must be used with an object-based FormView (e.g. CreateView)
    """
    def form_invalid(self, form):
        response = super(AjaxableResponseMixin, self).form_invalid(form)
        if self.request.is_ajax():
            return JsonResponse(form.errors, status=400)
        else:
            return response

    def form_valid(self, form):
        # We make sure to call the parent's form_valid() method because
        # it might do some processing (in the case of CreateView, it will
        # call form.save() for example).
        response = super(AjaxableResponseMixin, self).form_valid(form)
        if self.request.is_ajax():
            data = {
                'pk': self.object.pk,
            }
            return JsonResponse(data)
        else:
            return response

class AuthorCreate(AjaxableResponseMixin, CreateView):
    model = Author
    fields = ['name']

```

### 3.6.4 Using mixins with class-based views

**Caution:** This is an advanced topic. A working knowledge of *Django’s class-based views* is advised before exploring these techniques.

Django’s built-in class-based views provide a lot of functionality, but some of it you may want to use separately. For instance, you may want to write a view that renders a template to make the HTTP response, but you can’t use *TemplateView*; perhaps you need to render a template only on POST, with GET doing something else entirely. While you could use *TemplateResponse* directly, this will likely result in duplicate code.

For this reason, Django also provides a number of mixins that provide more discrete functionality. Template rendering, for instance, is encapsulated in the *TemplateResponseMixin*. The Django reference documentation contains *full documentation of all the mixins*.

## Context and template responses

Two central mixins are provided that help in providing a consistent interface to working with templates in class-based views.

**TemplateResponseMixin** Every built in view which returns a *TemplateResponse* will call the *render\_to\_response()* method that *TemplateResponseMixin* provides. Most of the time this will be called for you (for instance, it is called by the *get()* method implemented by both *TemplateView* and *DetailView*); similarly, it's unlikely that you'll need to override it, although if you want your response to return something not rendered via a Django template then you'll want to do it. For an example of this, see the *JSONResponseMixin example*.

*render\_to\_response()* itself calls *get\_template\_names()*, which by default will just look up *template\_name* on the class-based view; two other mixins (*SingleObjectTemplateResponseMixin* and *MultipleObjectTemplateResponseMixin*) override this to provide more flexible defaults when dealing with actual objects.

**ContextMixin** Every built in view which needs context data, such as for rendering a template (including *TemplateResponseMixin* above), should call *get\_context\_data()* passing any data they want to ensure is in there as keyword arguments. *get\_context\_data()* returns a dictionary; in *ContextMixin* it simply returns its keyword arguments, but it is common to override this to add more members to the dictionary.

## Building up Django's generic class-based views

Let's look at how two of Django's generic class-based views are built out of mixins providing discrete functionality. We'll consider *DetailView*, which renders a "detail" view of an object, and *ListView*, which will render a list of objects, typically from a queryset, and optionally paginate them. This will introduce us to four mixins which between them provide useful functionality when working with either a single Django object, or multiple objects.

There are also mixins involved in the generic edit views (*FormView*, and the model-specific views *CreateView*, *UpdateView* and *DeleteView*), and in the date-based generic views. These are covered in the *mixins reference documentation*.

### DetailView: working with a single Django object

To show the detail of an object, we basically need to do two things: we need to look up the object and then we need to make a *TemplateResponse* with a suitable template, and that object as context.

To get the object, *DetailView* relies on *SingleObjectMixin*, which provides a *get\_object()* method that figures out the object based on the URL of the request (it looks for *pk* and *slug* keyword arguments as declared in the *URLConf*, and looks the object up either from the *model* attribute on the view, or the *queryset* attribute if that's provided). *SingleObjectMixin* also overrides *get\_context\_data()*, which is used across all Django's built in class-based views to supply context data for template renders.

To then make a *TemplateResponse*, *DetailView* uses *SingleObjectTemplateResponseMixin*, which extends *TemplateResponseMixin*, overriding *get\_template\_names()* as discussed above. It actually provides a fairly sophisticated set of options, but the main one that most people are going to use is `<app_label>/<model_name>_detail.html`. The `_detail` part can be changed by setting *template\_name\_suffix* on a subclass to something else. (For instance, the *generic edit views* use `_form` for create and update views, and `_confirm_delete` for delete views.)

## ListView: working with many Django objects

Lists of objects follow roughly the same pattern: we need a (possibly paginated) list of objects, typically a *QuerySet*, and then we need to make a *TemplateResponse* with a suitable template using that list of objects.

To get the objects, *ListView* uses *MultipleObjectMixin*, which provides both *get\_queryset()* and *paginate\_queryset()*. Unlike with *SingleObjectMixin*, there's no need to key off parts of the URL to figure out the queryset to work with, so the default just uses the *queryset* or *model* attribute on the view class. A common reason to override *get\_queryset()* here would be to dynamically vary the objects, such as depending on the current user or to exclude posts in the future for a blog.

*MultipleObjectMixin* also overrides *get\_context\_data()* to include appropriate context variables for pagination (providing dummies if pagination is disabled). It relies on *object\_list* being passed in as a keyword argument, which *ListView* arranges for it.

To make a *TemplateResponse*, *ListView* then uses *MultipleObjectTemplateResponseMixin*; as with *SingleObjectTemplateResponseMixin* above, this overrides *get\_template\_names()* to provide a range of options, with the most commonly-used being `<app_label>/<model_name>_list.html`, with the `_list` part again being taken from the *template\_name\_suffix* attribute. (The date based generic views use suffixes such as `_archive`, `_archive_year` and so on to use different templates for the various specialized date-based list views.)

## Using Django's class-based view mixins

Now we've seen how Django's generic class-based views use the provided mixins, let's look at other ways we can combine them. Of course we're still going to be combining them with either built-in class-based views, or other generic class-based views, but there are a range of rarer problems you can solve than are provided for by Django out of the box.

**Warning:** Not all mixins can be used together, and not all generic class based views can be used with all other mixins. Here we present a few examples that do work; if you want to bring together other functionality then you'll have to consider interactions between attributes and methods that overlap between the different classes you're using, and how *method resolution order* will affect which versions of the methods will be called in what order.

The reference documentation for Django's *class-based views* and *class-based view mixins* will help you in understanding which attributes and methods are likely to cause conflict between different classes and mixins.

If in doubt, it's often better to back off and base your work on *View* or *TemplateView*, perhaps with *SingleObjectMixin* and *MultipleObjectMixin*. Although you will probably end up writing more code, it is more likely to be clearly understandable to someone else coming to it later, and with fewer interactions to worry about you will save yourself some thinking. (Of course, you can always dip into Django's implementation of the generic class-based views for inspiration on how to tackle problems.)

## Using SingleObjectMixin with View

If we want to write a simple class-based view that responds only to POST, we'll subclass *View* and write a *post()* method in the subclass. However if we want our processing to work on a particular object, identified from the URL, we'll want the functionality provided by *SingleObjectMixin*.

We'll demonstrate this with the *Author* model we used in the *generic class-based views introduction*.

```
views.py
from django.http import HttpResponseRedirect, HttpResponseRedirect
from django.urls import reverse
```

```
from django.views import View
from django.views.generic.detail import SingleObjectMixin
from books.models import Author

class RecordInterest(SingleObjectMixin, View):
    """Records the current user's interest in an author."""
    model = Author

    def post(self, request, *args, **kwargs):
        if not request.user.is_authenticated:
            return HttpResponseForbidden()

        # Look up the author we're interested in.
        self.object = self.get_object()
        # Actually record interest somehow here!

        return HttpResponseRedirect(reverse('author-detail', kwargs={'pk': self.object.pk}))
```

In practice you'd probably want to record the interest in a key-value store rather than in a relational database, so we've left that bit out. The only bit of the view that needs to worry about using *SingleObjectMixin* is where we want to look up the author we're interested in, which it just does with a simple call to `self.get_object()`. Everything else is taken care of for us by the mixin.

We can hook this into our URLs easily enough:

```
urls.py

from django.conf.urls import url
from books.views import RecordInterest

urlpatterns = [
    #...
    url(r'^author/(?P<pk>[0-9]+)/interest/$', RecordInterest.as_view(), name='author-interest'),
]
```

Note the `pk` named group, which `get_object()` uses to look up the `Author` instance. You could also use a slug, or any of the other features of *SingleObjectMixin*.

## Using *SingleObjectMixin* with *ListView*

*ListView* provides built-in pagination, but you might want to paginate a list of objects that are all linked (by a foreign key) to another object. In our publishing example, you might want to paginate through all the books by a particular publisher.

One way to do this is to combine *ListView* with *SingleObjectMixin*, so that the queryset for the paginated list of books can hang off the publisher found as the single object. In order to do this, we need to have two different querysets:

**Book queryset for use by *ListView*** Since we have access to the `Publisher` whose books we want to list, we simply override `get_queryset()` and use the `Publisher`'s *reverse foreign key manager*.

**Publisher queryset for use in `get_object()`** We'll rely on the default implementation of `get_object()` to fetch the correct `Publisher` object. However, we need to explicitly pass a `queryset` argument because otherwise the default implementation of `get_object()` would call `get_queryset()` which we have overridden to return `Book` objects instead of `Publisher` ones.

---

**Note:** We have to think carefully about `get_context_data()`. Since both *SingleObjectMixin* and *ListView* will put things in the context data under the value of `context_object_name` if it's set, we'll in-

stead explicitly ensure the Publisher is in the context data. `ListView` will add in the suitable `page_obj` and `paginator` for us providing we remember to call `super()`.

Now we can write a new `PublisherDetail`:

```
from django.views.generic import ListView
from django.views.generic.detail import SingleObjectMixin
from books.models import Publisher

class PublisherDetail(SingleObjectMixin, ListView):
    paginate_by = 2
    template_name = "books/publisher_detail.html"

    def get(self, request, *args, **kwargs):
        self.object = self.get_object(queryset=Publisher.objects.all())
        return super(PublisherDetail, self).get(request, *args, **kwargs)

    def get_context_data(self, **kwargs):
        context = super(PublisherDetail, self).get_context_data(**kwargs)
        context['publisher'] = self.object
        return context

    def get_queryset(self):
        return self.object.book_set.all()
```

Notice how we set `self.object` within `get()` so we can use it again later in `get_context_data()` and `get_queryset()`. If you don't set `template_name`, the template will default to the normal `ListView` choice, which in this case would be `"books/book_list.html"` because it's a list of books; `ListView` knows nothing about `SingleObjectMixin`, so it doesn't have any clue this view is anything to do with a `Publisher`.

The `paginate_by` is deliberately small in the example so you don't have to create lots of books to see the pagination working! Here's the template you'd want to use:

```
{% extends "base.html" %}

{% block content %}
    <h2>Publisher {{ publisher.name }}</h2>

    <ol>
        {% for book in page_obj %}
            <li>{{ book.title }}</li>
        {% endfor %}
    </ol>

    <div class="pagination">
        <span class="step-links">
            {% if page_obj.has_previous %}
                <a href="?page={{ page_obj.previous_page_number }}">previous</a>
            {% endif %}

            <span class="current">
                Page {{ page_obj.number }} of {{ paginator.num_pages }}.
            </span>

            {% if page_obj.has_next %}
                <a href="?page={{ page_obj.next_page_number }}">next</a>
            {% endif %}
        </span>
    </div>
```

```
</div>
{% endblock %}
```

## Avoid anything more complex

Generally you can use `TemplateResponseMixin` and `SingleObjectMixin` when you need their functionality. As shown above, with a bit of care you can even combine `SingleObjectMixin` with `ListView`. However things get increasingly complex as you try to do so, and a good rule of thumb is:

---

**Hint:** Each of your views should use only mixins or views from one of the groups of generic class-based views: *detail*, *list*, *editing* and *date*. For example it's fine to combine `TemplateView` (built in view) with `MultipleObjectMixin` (generic list), but you're likely to have problems combining `SingleObjectMixin` (generic detail) with `MultipleObjectMixin` (generic list).

---

To show what happens when you try to get more sophisticated, we show an example that sacrifices readability and maintainability when there is a simpler solution. First, let's look at a naive attempt to combine `DetailView` with `FormMixin` to enable us to POST a Django `Form` to the same URL as we're displaying an object using `DetailView`.

## Using FormMixin with DetailView

Think back to our earlier example of using `View` and `SingleObjectMixin` together. We were recording a user's interest in a particular author; say now that we want to let them leave a message saying why they like them. Again, let's assume we're not going to store this in a relational database but instead in something more esoteric that we won't worry about here.

At this point it's natural to reach for a `Form` to encapsulate the information sent from the user's browser to Django. Say also that we're heavily invested in REST, so we want to use the same URL for displaying the author as for capturing the message from the user. Let's rewrite our `AuthorDetailView` to do that.

We'll keep the GET handling from `DetailView`, although we'll have to add a `Form` into the context data so we can render it in the template. We'll also want to pull in form processing from `FormMixin`, and write a bit of code so that on POST the form gets called appropriately.

---

**Note:** We use `FormMixin` and implement `post()` ourselves rather than try to mix `DetailView` with `FormView` (which provides a suitable `post()` already) because both of the views implement `get()`, and things would get much more confusing.

---

Our new `AuthorDetail` looks like this:

```
# CAUTION: you almost certainly do not want to do this.
# It is provided as part of a discussion of problems you can
# run into when combining different generic class-based view
# functionality that is not designed to be used together.

from django import forms
from django.http import HttpResponseRedirect
from django.urls import reverse
from django.views.generic import DetailView
from django.views.generic.edit import FormMixin
from books.models import Author
```

```

class AuthorInterestForm(forms.Form):
    message = forms.CharField()

class AuthorDetail(FormMixin, DetailView):
    model = Author
    form_class = AuthorInterestForm

    def get_success_url(self):
        return reverse('author-detail', kwargs={'pk': self.object.pk})

    def get_context_data(self, **kwargs):
        context = super(AuthorDetail, self).get_context_data(**kwargs)
        context['form'] = self.get_form()
        return context

    def post(self, request, *args, **kwargs):
        if not request.user.is_authenticated:
            return HttpResponseForbidden()
        self.object = self.get_object()
        form = self.get_form()
        if form.is_valid():
            return self.form_valid(form)
        else:
            return self.form_invalid(form)

    def form_valid(self, form):
        # Here, we would record the user's interest using the message
        # passed in form.cleaned_data['message']
        return super(AuthorDetail, self).form_valid(form)

```

`get_success_url()` is just providing somewhere to redirect to, which gets used in the default implementation of `form_valid()`. We have to provide our own `post()` as noted earlier, and override `get_context_data()` to make the *Form* available in the context data.

## A better solution

It should be obvious that the number of subtle interactions between *FormMixin* and *DetailView* is already testing our ability to manage things. It's unlikely you'd want to write this kind of class yourself.

In this case, it would be fairly easy to just write the `post()` method yourself, keeping *DetailView* as the only generic functionality, although writing *Form* handling code involves a lot of duplication.

Alternatively, it would still be easier than the above approach to have a separate view for processing the form, which could use *FormView* distinct from *DetailView* without concerns.

## An alternative better solution

What we're really trying to do here is to use two different class based views from the same URL. So why not do just that? We have a very clear division here: GET requests should get the *DetailView* (with the *Form* added to the context data), and POST requests should get the *FormView*. Let's set up those views first.

The *AuthorDisplay* view is almost the same as *when we first introduced AuthorDetail*; we have to write our own `get_context_data()` to make the *AuthorInterestForm* available to the template. We'll skip the `get_object()` override from before for clarity:

```
from django.views.generic import DetailView
from django import forms
from books.models import Author

class AuthorInterestForm(forms.Form):
    message = forms.CharField()

class AuthorDisplay(DetailView):
    model = Author

    def get_context_data(self, **kwargs):
        context = super(AuthorDisplay, self).get_context_data(**kwargs)
        context['form'] = AuthorInterestForm()
        return context
```

Then the `AuthorInterest` is a simple `FormView`, but we have to bring in `SingleObjectMixin` so we can find the author we're talking about, and we have to remember to set `template_name` to ensure that form errors will render the same template as `AuthorDisplay` is using on GET:

```
from django.urls import reverse
from django.http import HttpResponseForbidden
from django.views.generic import FormView
from django.views.generic.detail import SingleObjectMixin

class AuthorInterest(SingleObjectMixin, FormView):
    template_name = 'books/author_detail.html'
    form_class = AuthorInterestForm
    model = Author

    def post(self, request, *args, **kwargs):
        if not request.user.is_authenticated:
            return HttpResponseForbidden()
        self.object = self.get_object()
        return super(AuthorInterest, self).post(request, *args, **kwargs)

    def get_success_url(self):
        return reverse('author-detail', kwargs={'pk': self.object.pk})
```

Finally we bring this together in a new `AuthorDetail` view. We already know that calling `as_view()` on a class-based view gives us something that behaves exactly like a function based view, so we can do that at the point we choose between the two subviews.

You can of course pass through keyword arguments to `as_view()` in the same way you would in your `URLconf`, such as if you wanted the `AuthorInterest` behavior to also appear at another URL but using a different template:

```
from django.views import View

class AuthorDetail(View):

    def get(self, request, *args, **kwargs):
        view = AuthorDisplay.as_view()
        return view(request, *args, **kwargs)

    def post(self, request, *args, **kwargs):
        view = AuthorInterest.as_view()
        return view(request, *args, **kwargs)
```

This approach can also be used with any other generic class-based views or your own class-based views inheriting

directly from `View` or `TemplateView`, as it keeps the different views as separate as possible.

## More than just HTML

Where class-based views shine is when you want to do the same thing many times. Suppose you're writing an API, and every view should return JSON instead of rendered HTML.

We can create a mixin class to use in all of our views, handling the conversion to JSON once.

For example, a simple JSON mixin might look something like this:

```
from django.http import JsonResponse

class JsonResponseMixin(object):
    """
    A mixin that can be used to render a JSON response.
    """
    def render_to_json_response(self, context, **response_kwargs):
        """
        Returns a JSON response, transforming 'context' to make the payload.
        """
        return JsonResponse(
            self.get_data(context),
            **response_kwargs
        )

    def get_data(self, context):
        """
        Returns an object that will be serialized as JSON by json.dumps().
        """
        # Note: This is *EXTREMELY* naive; in reality, you'll need
        # to do much more complex handling to ensure that arbitrary
        # objects -- such as Django model instances or querysets
        # -- can be serialized as JSON.
        return context
```

**Note:** Check out the [Serializing Django objects](#) documentation for more information on how to correctly transform Django models and querysets into JSON.

This mixin provides a `render_to_json_response()` method with the same signature as `render_to_response()`. To use it, we simply need to mix it into a `TemplateView` for example, and override `render_to_response()` to call `render_to_json_response()` instead:

```
from django.views.generic import TemplateView

class JSONView(JsonResponseMixin, TemplateView):
    def render_to_response(self, context, **response_kwargs):
        return self.render_to_json_response(context, **response_kwargs)
```

Equally we could use our mixin with one of the generic views. We can make our own version of `DetailView` by mixing `JsonResponseMixin` with the `django.views.generic.detail.BaseDetailView` – (the `DetailView` before template rendering behavior has been mixed in):

```
from django.views.generic.detail import BaseDetailView

class JSONDetailView(JsonResponseMixin, BaseDetailView):
```

```
def render_to_response(self, context, **response_kwargs):
    return self.render_to_json_response(context, **response_kwargs)
```

This view can then be deployed in the same way as any other *DetailView*, with exactly the same behavior – except for the format of the response.

If you want to be really adventurous, you could even mix a *DetailView* subclass that is able to return *both* HTML and JSON content, depending on some property of the HTTP request, such as a query argument or a HTTP header. Just mix in both the *JSONResponseMixin* and a *SingleObjectTemplateResponseMixin*, and override the implementation of *render\_to\_response()* to defer to the appropriate rendering method depending on the type of response that the user requested:

```
from django.views.generic.detail import SingleObjectTemplateResponseMixin

class HybridDetailView(JSONResponseMixin, SingleObjectTemplateResponseMixin,
↳BaseDetailView):
    def render_to_response(self, context):
        # Look for a 'format=json' GET argument
        if self.request.GET.get('format') == 'json':
            return self.render_to_json_response(context)
        else:
            return super(HybridDetailView, self).render_to_response(context)
```

Because of the way that Python resolves method overloading, the call to `super(HybridDetailView, self).render_to_response(context)` ends up calling the *render\_to\_response()* implementation of *TemplateResponseMixin*.

### 3.6.5 Basic examples

Django provides base view classes which will suit a wide range of applications. All views inherit from the *View* class, which handles linking the view in to the URLs, HTTP method dispatching and other simple features. *RedirectView* is for a simple HTTP redirect, and *TemplateView* extends the base class to make it also render a template.

### 3.6.6 Simple usage in your URLconf

The simplest way to use generic views is to create them directly in your URLconf. If you're only changing a few simple attributes on a class-based view, you can simply pass them into the *as\_view()* method call itself:

```
from django.conf.urls import url
from django.views.generic import TemplateView

urlpatterns = [
    url(r'^about/$', TemplateView.as_view(template_name="about.html")),
]
```

Any arguments passed to *as\_view()* will override attributes set on the class. In this example, we set `template_name` on the *TemplateView*. A similar overriding pattern can be used for the `url` attribute on *RedirectView*.

### 3.6.7 Subclassing generic views

The second, more powerful way to use generic views is to inherit from an existing view and override attributes (such as the `template_name`) or methods (such as `get_context_data`) in your subclass to provide new values or methods. Consider, for example, a view that just displays one template, `about.html`. Django has a generic view to do this - `TemplateView` - so we can just subclass it, and override the template name:

```
# some_app/views.py
from django.views.generic import TemplateView

class AboutView(TemplateView):
    template_name = "about.html"
```

Then we just need to add this new view into our URLconf. `TemplateView` is a class, not a function, so we point the URL to the `as_view()` class method instead, which provides a function-like entry to class-based views:

```
# urls.py
from django.conf.urls import url
from some_app.views import AboutView

urlpatterns = [
    url(r'^about/$', AboutView.as_view()),
]
```

For more information on how to use the built in generic views, consult the next topic on *generic class-based views*.

### Supporting other HTTP methods

Suppose somebody wants to access our book library over HTTP using the views as an API. The API client would connect every now and then and download book data for the books published since last visit. But if no new books appeared since then, it is a waste of CPU time and bandwidth to fetch the books from the database, render a full response and send it to the client. It might be preferable to ask the API when the most recent book was published.

We map the URL to book list view in the URLconf:

```
from django.conf.urls import url
from books.views import BookListView

urlpatterns = [
    url(r'^books/$', BookListView.as_view()),
]
```

And the view:

```
from django.http import HttpResponse
from django.views.generic import ListView
from books.models import Book

class BookListView(ListView):
    model = Book

    def head(self, *args, **kwargs):
        last_book = self.get_queryset().latest('publication_date')
        response = HttpResponse('')
        # RFC 1123 date format
```

```
response['Last-Modified'] = last_book.publication_date.strftime('%a, %d %b %Y
↪%H:%M:%S GMT')
return response
```

If the view is accessed from a GET request, a plain-and-simple object list is returned in the response (using `book_list.html` template). But if the client issues a HEAD request, the response has an empty body and the `Last-Modified` header indicates when the most recent book was published. Based on this information, the client may or may not download the full object list.

## 3.7 Migrations

Migrations are Django’s way of propagating changes you make to your models (adding a field, deleting a model, etc.) into your database schema. They’re designed to be mostly automatic, but you’ll need to know when to make migrations, when to run them, and the common problems you might run into.

### 3.7.1 The Commands

There are several commands which you will use to interact with migrations and Django’s handling of database schema:

- `migrate`, which is responsible for applying and unapplying migrations.
- `makemigrations`, which is responsible for creating new migrations based on the changes you have made to your models.
- `sqlmigrate`, which displays the SQL statements for a migration.
- `showmigrations`, which lists a project’s migrations and their status.

You should think of migrations as a version control system for your database schema. `makemigrations` is responsible for packaging up your model changes into individual migration files - analogous to commits - and `migrate` is responsible for applying those to your database.

The migration files for each app live in a “migrations” directory inside of that app, and are designed to be committed to, and distributed as part of, its codebase. You should be making them once on your development machine and then running the same migrations on your colleagues’ machines, your staging machines, and eventually your production machines.

---

**Note:** It is possible to override the name of the package which contains the migrations on a per-app basis by modifying the `MIGRATION_MODULES` setting.

---

Migrations will run the same way on the same dataset and produce consistent results, meaning that what you see in development and staging is, under the same circumstances, exactly what will happen in production.

Django will make migrations for any change to your models or fields - even options that don’t affect the database - as the only way it can reconstruct a field correctly is to have all the changes in the history, and you might need those options in some data migrations later on (for example, if you’ve set custom validators).

### 3.7.2 Backend Support

Migrations are supported on all backends that Django ships with, as well as any third-party backends if they have programmed in support for schema alteration (done via the `SchemaEditor` class).

However, some databases are more capable than others when it comes to schema migrations; some of the caveats are covered below.

## PostgreSQL

PostgreSQL is the most capable of all the databases here in terms of schema support; the only caveat is that adding columns with default values will cause a full rewrite of the table, for a time proportional to its size.

For this reason, it's recommended you always create new columns with `null=True`, as this way they will be added immediately.

## MySQL

MySQL lacks support for transactions around schema alteration operations, meaning that if a migration fails to apply you will have to manually unpick the changes in order to try again (it's impossible to roll back to an earlier point).

In addition, MySQL will fully rewrite tables for almost every schema operation and generally takes a time proportional to the number of rows in the table to add or remove columns. On slower hardware this can be worse than a minute per million rows - adding a few columns to a table with just a few million rows could lock your site up for over ten minutes.

Finally, MySQL has relatively small limits on name lengths for columns, tables and indexes, as well as a limit on the combined size of all columns an index covers. This means that indexes that are possible on other backends will fail to be created under MySQL.

## SQLite

SQLite has very little built-in schema alteration support, and so Django attempts to emulate it by:

- Creating a new table with the new schema
- Copying the data across
- Dropping the old table
- Renaming the new table to match the original name

This process generally works well, but it can be slow and occasionally buggy. It is not recommended that you run and migrate SQLite in a production environment unless you are very aware of the risks and its limitations; the support Django ships with is designed to allow developers to use SQLite on their local machines to develop less complex Django projects without the need for a full database.

### 3.7.3 Workflow

Working with migrations is simple. Make changes to your models - say, add a field and remove a model - and then run `makemigrations`:

```
$ python manage.py makemigrations
Migrations for 'books':
  books/migrations/0003_auto.py:
    - Alter field author on book
```

Your models will be scanned and compared to the versions currently contained in your migration files, and then a new set of migrations will be written out. Make sure to read the output to see what `makemigrations` thinks you have changed - it's not perfect, and for complex changes it might not be detecting what you expect.

Once you have your new migration files, you should apply them to your database to make sure they work as expected:

```
$ python manage.py migrate
Operations to perform:
  Apply all migrations: books
Running migrations:
  Rendering model states... DONE
  Applying books.0003_auto... OK
```

Once the migration is applied, commit the migration and the models change to your version control system as a single commit - that way, when other developers (or your production servers) check out the code, they'll get both the changes to your models and the accompanying migration at the same time.

If you want to give the migration(s) a meaningful name instead of a generated one, you can use the `makemigrations --name` option:

```
$ python manage.py makemigrations --name changed_my_model your_app_label
```

## Version control

Because migrations are stored in version control, you'll occasionally come across situations where you and another developer have both committed a migration to the same app at the same time, resulting in two migrations with the same number.

Don't worry - the numbers are just there for developers' reference, Django just cares that each migration has a different name. Migrations specify which other migrations they depend on - including earlier migrations in the same app - in the file, so it's possible to detect when there's two new migrations for the same app that aren't ordered.

When this happens, Django will prompt you and give you some options. If it thinks it's safe enough, it will offer to automatically linearize the two migrations for you. If not, you'll have to go in and modify the migrations yourself - don't worry, this isn't difficult, and is explained more in *Migration files* below.

### 3.7.4 Dependencies

While migrations are per-app, the tables and relationships implied by your models are too complex to be created for just one app at a time. When you make a migration that requires something else to run - for example, you add a `ForeignKey` in your `books` app to your `authors` app - the resulting migration will contain a dependency on a migration in `authors`.

This means that when you run the migrations, the `authors` migration runs first and creates the table the `ForeignKey` references, and then the migration that makes the `ForeignKey` column runs afterwards and creates the constraint. If this didn't happen, the migration would try to create the `ForeignKey` column without the table it's referencing existing and your database would throw an error.

This dependency behavior affects most migration operations where you restrict to a single app. Restricting to a single app (either in `makemigrations` or `migrate`) is a best-efforts promise, and not a guarantee; any other apps that need to be used to get dependencies correct will be.

### 3.7.5 Migration files

Migrations are stored as an on-disk format, referred to here as "migration files". These files are actually just normal Python files with an agreed-upon object layout, written in a declarative style.

A basic migration file looks like this:

```

from django.db import migrations, models

class Migration(migrations.Migration):

    dependencies = [("migrations", "0001_initial")]

    operations = [
        migrations.DeleteModel("Tribble"),
        migrations.AddField("Author", "rating", models.IntegerField(default=0)),
    ]

```

What Django looks for when it loads a migration file (as a Python module) is a subclass of `django.db.migrations.Migration` called `Migration`. It then inspects this object for four attributes, only two of which are used most of the time:

- `dependencies`, a list of migrations this one depends on.
- `operations`, a list of `Operation` classes that define what this migration does.

The operations are the key; they are a set of declarative instructions which tell Django what schema changes need to be made. Django scans them and builds an in-memory representation of all of the schema changes to all apps, and uses this to generate the SQL which makes the schema changes.

That in-memory structure is also used to work out what the differences are between your models and the current state of your migrations; Django runs through all the changes, in order, on an in-memory set of models to come up with the state of your models last time you ran `makemigrations`. It then uses these models to compare against the ones in your `models.py` files to work out what you have changed.

You should rarely, if ever, need to edit migration files by hand, but it's entirely possible to write them manually if you need to. Some of the more complex operations are not autodetectable and are only available via a hand-written migration, so don't be scared about editing them if you have to.

## Custom fields

You can't modify the number of positional arguments in an already migrated custom field without raising a `TypeError`. The old migration will call the modified `__init__` method with the old signature. So if you need a new argument, please create a keyword argument and add something like `assert 'argument_name' in kwargs` in the constructor.

## Model managers

You can optionally serialize managers into migrations and have them available in *RunPython* operations. This is done by defining a `use_in_migrations` attribute on the manager class:

```

class MyManager(models.Manager):
    use_in_migrations = True

class MyModel(models.Model):
    objects = MyManager()

```

If you are using the `from_queryset()` function to dynamically generate a manager class, you need to inherit from the generated class to make it importable:

```

class MyManager(MyBaseManager.from_queryset(CustomQuerySet)):
    use_in_migrations = True

```

```
class MyModel(models.Model):
    objects = MyManager()
```

Please refer to the notes about *Historical models* in migrations to see the implications that come along.

## Initial migrations

### Migration.`initial`

The “initial migrations” for an app are the migrations that create the first version of that app’s tables. Usually an app will have just one initial migration, but in some cases of complex model interdependencies it may have two or more.

Initial migrations are marked with an `initial = True` class attribute on the migration class. If an `initial` class attribute isn’t found, a migration will be considered “initial” if it is the first migration in the app (i.e. if it has no dependencies on any other migration in the same app).

When the `migrate --fake-initial` option is used, these initial migrations are treated specially. For an initial migration that creates one or more tables (`CreateModel` operation), Django checks that all of those tables already exist in the database and fake-applies the migration if so. Similarly, for an initial migration that adds one or more fields (`AddField` operation), Django checks that all of the respective columns already exist in the database and fake-applies the migration if so. Without `--fake-initial`, initial migrations are treated no differently from any other migration.

## History consistency

As previously discussed, you may need to linearize migrations manually when two development branches are joined. While editing migration dependencies, you can inadvertently create an inconsistent history state where a migration has been applied but some of its dependencies haven’t. This is a strong indication that the dependencies are incorrect, so Django will refuse to run migrations or make new migrations until it’s fixed. When using multiple databases, you can use the `allow_migrate()` method of *database routers* to control which databases `makemigrations` checks for consistent history.

Migration consistency checks were added. Checks based on database routers were added in 1.10.1.

### 3.7.6 Adding migrations to apps

Adding migrations to new apps is straightforward - they come preconfigured to accept migrations, and so just run `makemigrations` once you’ve made some changes.

If your app already has models and database tables, and doesn’t have migrations yet (for example, you created it against a previous Django version), you’ll need to convert it to use migrations; this is a simple process:

```
$ python manage.py makemigrations your_app_label
```

This will make a new initial migration for your app. Now, run `python manage.py migrate --fake-initial`, and Django will detect that you have an initial migration *and* that the tables it wants to create already exist, and will mark the migration as already applied. (Without the `migrate --fake-initial` flag, the command would error out because the tables it wants to create already exist.)

Note that this only works given two things:

- You have not changed your models since you made their tables. For migrations to work, you must make the initial migration *first* and then make changes, as Django compares changes against migration files, not the database.

- You have not manually edited your database - Django won't be able to detect that your database doesn't match your models, you'll just get errors when migrations try to modify those tables.

### 3.7.7 Historical models

When you run migrations, Django is working from historical versions of your models stored in the migration files. If you write Python code using the *RunPython* operation, or if you have `allow_migrate` methods on your database routers, you will be exposed to these versions of your models.

Because it's impossible to serialize arbitrary Python code, these historical models will not have any custom methods that you have defined. They will, however, have the same fields, relationships, managers (limited to those with `use_in_migrations = True`) and Meta options (also versioned, so they may be different from your current ones).

**Warning:** This means that you will NOT have custom `save()` methods called on objects when you access them in migrations, and you will NOT have any custom constructors or instance methods. Plan appropriately!

References to functions in field options such as `upload_to` and `limit_choices_to` and model manager declarations with managers having `use_in_migrations = True` are serialized in migrations, so the functions and classes will need to be kept around for as long as there is a migration referencing them. Any *custom model fields* will also need to be kept, since these are imported directly by migrations.

In addition, the base classes of the model are just stored as pointers, so you must always keep base classes around for as long as there is a migration that contains a reference to them. On the plus side, methods and managers from these base classes inherit normally, so if you absolutely need access to these you can opt to move them into a superclass.

To remove old references, you can *squash migrations* or, if there aren't many references, copy them into the migration files.

### 3.7.8 Considerations when removing model fields

Similar to the “references to historical functions” considerations described in the previous section, removing custom model fields from your project or third-party app will cause a problem if they are referenced in old migrations.

To help with this situation, Django provides some model field attributes to assist with model field deprecation using the *system checks framework*.

Add the `system_check_deprecated_details` attribute to your model field similar to the following:

```
class IPAddressField(Field):
    system_check_deprecated_details = {
        'msg': (
            'IPAddressField has been deprecated. Support for it (except '
            'in historical migrations) will be removed in Django 1.9.'
        ),
        'hint': 'Use GenericIPAddressField instead.', # optional
        'id': 'fields.W900', # pick a unique ID for your field.
    }
```

After a deprecation period of your choosing (two or three feature releases for fields in Django itself), change the `system_check_deprecated_details` attribute to `system_check_removed_details` and update the dictionary similar to:

```
class IPAddressField(Field):
    system_check_removed_details = {
        'msg': (
            'IPAddressField has been removed except for support in '
            'historical migrations.'
        ),
        'hint': 'Use GenericIPAddressField instead.',
        'id': 'fields.E900', # pick a unique ID for your field.
    }
```

You should keep the field’s methods that are required for it to operate in database migrations such as `__init__()`, `deconstruct()`, and `get_internal_type()`. Keep this stub field for as long as any migrations which reference the field exist. For example, after squashing migrations and removing the old ones, you should be able to remove the field completely.

### 3.7.9 Data Migrations

As well as changing the database schema, you can also use migrations to change the data in the database itself, in conjunction with the schema if you want.

Migrations that alter data are usually called “data migrations”; they’re best written as separate migrations, sitting alongside your schema migrations.

Django can’t automatically generate data migrations for you, as it does with schema migrations, but it’s not very hard to write them. Migration files in Django are made up of *Operations*, and the main operation you use for data migrations is *RunPython*.

To start, make an empty migration file you can work from (Django will put the file in the right place, suggest a name, and add dependencies for you):

```
python manage.py makemigrations --empty yourappname
```

Then, open up the file; it should look something like this:

```
# -*- coding: utf-8 -*-
# Generated by Django A.B on YYYY-MM-DD HH:MM
from __future__ import unicode_literals

from django.db import migrations, models

class Migration(migrations.Migration):

    dependencies = [
        ('yourappname', '0001_initial'),
    ]

    operations = [
    ]
```

Now, all you need to do is create a new function and have *RunPython* use it. *RunPython* expects a callable as its argument which takes two arguments - the first is an *app registry* that has the historical versions of all your models loaded into it to match where in your history the migration sits, and the second is a *SchemaEditor*, which you can use to manually effect database schema changes (but beware, doing this can confuse the migration autodetector!)

Let’s write a simple migration that populates our new `name` field with the combined values of `first_name` and `last_name` (we’ve come to our senses and realized that not everyone has first and last names). All we need to do is use the historical model and iterate over the rows:

```
# -*- coding: utf-8 -*-
from __future__ import unicode_literals

from django.db import migrations, models

def combine_names(apps, schema_editor):
    # We can't import the Person model directly as it may be a newer
    # version than this migration expects. We use the historical version.
    Person = apps.get_model("yourappname", "Person")
    for person in Person.objects.all():
        person.name = "%s %s" % (person.first_name, person.last_name)
        person.save()

class Migration(migrations.Migration):

    dependencies = [
        ('yourappname', '0001_initial'),
    ]

    operations = [
        migrations.RunPython(combine_names),
    ]
```

Once that's done, we can just run `python manage.py migrate` as normal and the data migration will run in place alongside other migrations.

You can pass a second callable to `RunPython` to run whatever logic you want executed when migrating backwards. If this callable is omitted, migrating backwards will raise an exception.

### Accessing models from other apps

When writing a `RunPython` function that uses models from apps other than the one in which the migration is located, the migration's `dependencies` attribute should include the latest migration of each app that is involved, otherwise you may get an error similar to: `LookupError: No installed app with label 'myappname' when you try to retrieve the model in the RunPython function using apps.get_model()`.

In the following example, we have a migration in `app1` which needs to use models in `app2`. We aren't concerned with the details of `move_m1` other than the fact it will need to access models from both apps. Therefore we've added a dependency that specifies the last migration of `app2`:

```
class Migration(migrations.Migration):

    dependencies = [
        ('app1', '0001_initial'),
        # added dependency to enable using models from app2 in move_m1
        ('app2', '0004_foobar'),
    ]

    operations = [
        migrations.RunPython(move_m1),
    ]
```

### More advanced migrations

If you're interested in the more advanced migration operations, or want to be able to write your own, see the [migration operations reference](#) and the “how-to” on [writing migrations](#).

### 3.7.10 Squashing migrations

You are encouraged to make migrations freely and not worry about how many you have; the migration code is optimized to deal with hundreds at a time without much slowdown. However, eventually you will want to move back from having several hundred migrations to just a few, and that's where squashing comes in.

Squashing is the act of reducing an existing set of many migrations down to one (or sometimes a few) migrations which still represent the same changes.

Django does this by taking all of your existing migrations, extracting their `Operations` and putting them all in sequence, and then running an optimizer over them to try and reduce the length of the list - for example, it knows that `CreateModel` and `DeleteModel` cancel each other out, and it knows that `AddField` can be rolled into `CreateModel`.

Once the operation sequence has been reduced as much as possible - the amount possible depends on how closely intertwined your models are and if you have any `RunSQL` or `RunPython` operations (which can't be optimized through unless they are marked as `elidable`) - Django will then write it back out into a new set of migration files.

These files are marked to say they replace the previously-squashed migrations, so they can coexist with the old migration files, and Django will intelligently switch between them depending where you are in the history. If you're still part-way through the set of migrations that you squashed, it will keep using them until it hits the end and then switch to the squashed history, while new installs will just use the new squashed migration and skip all the old ones.

This enables you to squash and not mess up systems currently in production that aren't fully up-to-date yet. The recommended process is to squash, keep the old files, commit and release, wait until all systems are upgraded with the new release (or if you're a third-party project, just ensure your users upgrade releases in order without skipping any), and then remove the old files, commit and do a second release.

The command that backs all this is `squashmigrations` - just pass it the app label and migration name you want to squash up to, and it'll get to work:

```
$ ./manage.py squashmigrations myapp 0004
Will squash the following migrations:
- 0001_initial
- 0002_some_change
- 0003_another_change
- 0004_undo_something
Do you wish to proceed? [yN] y
Optimizing...
  Optimized from 12 operations to 7 operations.
Created new squashed migration /home/andrew/Programs/DjangoTest/test/migrations/0001_
↪squashed_0004_undo_something.py
  You should commit this migration but leave the old ones in place;
  the new migration will be used for new installs. Once you are sure
  all instances of the codebase have applied the migrations you squashed,
  you can delete them.
```

Note that model interdependencies in Django can get very complex, and squashing may result in migrations that do not run; either mis-optimized (in which case you can try again with `--no-optimize`, though you should also report an issue), or with a `CircularDependencyError`, in which case you can manually resolve it.

To manually resolve a `CircularDependencyError`, break out one of the `ForeignKeys` in the circular dependency loop into a separate migration, and move the dependency on the other app with it. If you're unsure, see how `makemigrations` deals with the problem when asked to create brand new migrations from your models. In a future release of Django, `squashmigrations` will be updated to attempt to resolve these errors itself.

Once you've squashed your migration, you should then commit it alongside the migrations it replaces and distribute this change to all running instances of your application, making sure that they run `migrate` to store the change in their database.

You must then transition the squashed migration to a normal migration by:

- Deleting all the migration files it replaces.
- Updating all migrations that depend on the deleted migrations to depend on the squashed migration instead.
- Removing the `replaces` attribute in the `Migration` class of the squashed migration (this is how Django tells that it is a squashed migration).

---

**Note:** Once you've squashed a migration, you should not then re-squash that squashed migration until you have fully transitioned it to a normal migration.

---

### 3.7.11 Serializing values

Migrations are just Python files containing the old definitions of your models - thus, to write them, Django must take the current state of your models and serialize them out into a file.

While Django can serialize most things, there are some things that we just can't serialize out into a valid Python representation - there's no Python standard for how a value can be turned back into code (`repr()` only works for basic values, and doesn't specify import paths).

Django can serialize the following:

- `int`, `long`, `float`, `bool`, `str`, `unicode`, `bytes`, `None`
- `list`, `set`, `tuple`, `dict`
- `datetime.date`, `datetime.time`, and `datetime.datetime` instances (include those that are `timezone-aware`)
- `decimal.Decimal` instances
- `enum.Enum` instances
- `functools.partial` instances which have `serializable func`, `args`, and `keywords` values.
- `LazyObject` instances which wrap a serializable value.
- Any Django field
- Any function or method reference (e.g. `datetime.datetime.today`) (must be in module's top-level scope)
- Any class reference (must be in module's top-level scope)
- Anything with a custom `deconstruct()` method (*see below*)

Serialization support for `functools.partial` and `LazyObject` instances was added.

Serialization support for `enum.Enum` was added.

Django can serialize the following on Python 3 only:

- Unbound methods used from within the class body (see below)

Django cannot serialize:

- Nested classes
- Arbitrary class instances (e.g. `MyClass(4.3, 5.7)`)
- Lambdas

Due to the fact `__qualname__` was only introduced in Python 3, Django can only serialize the following pattern (an unbound method used within the class body) on Python 3, and will fail to serialize a reference to it on Python 2:

```
class MyModel(models.Model):

    def upload_to(self):
        return "something dynamic"

my_file = models.FileField(upload_to=upload_to)
```

If you are using Python 2, we recommend you move your methods for `upload_to` and similar arguments that accept callables (e.g. `default`) to live in the main module body, rather than the class body.

### Adding a `deconstruct()` method

You can let Django serialize your own custom class instances by giving the class a `deconstruct()` method. It takes no arguments, and should return a tuple of three things (`path`, `args`, `kwargs`):

- `path` should be the Python path to the class, with the class name included as the last part (for example, `myapp.custom_things.MyClass`). If your class is not available at the top level of a module it is not serializable.
- `args` should be a list of positional arguments to pass to your class' `__init__` method. Everything in this list should itself be serializable.
- `kwargs` should be a dict of keyword arguments to pass to your class' `__init__` method. Every value should itself be serializable.

---

**Note:** This return value is different from the `deconstruct()` method *for custom fields* which returns a tuple of four items.

---

Django will write out the value as an instantiation of your class with the given arguments, similar to the way it writes out references to Django fields.

To prevent a new migration from being created each time `makemigrations` is run, you should also add a `__eq__()` method to the decorated class. This function will be called by Django's migration framework to detect changes between states.

As long as all of the arguments to your class' constructor are themselves serializable, you can use the `@deconstructible` class decorator from `django.utils.deconstruct` to add the `deconstruct()` method:

```
from django.utils.deconstruct import deconstructible

@deconstructible
class MyCustomClass(object):

    def __init__(self, foo=1):
        self.foo = foo
        ...

    def __eq__(self, other):
        return self.foo == other.foo
```

The decorator adds logic to capture and preserve the arguments on their way into your constructor, and then returns those arguments exactly when `deconstruct()` is called.

### 3.7.12 Supporting Python 2 and 3

In order to generate migrations that support both Python 2 and 3, all string literals used in your models and fields (e.g. `verbose_name`, `related_name`, etc.), must be consistently either bytestrings or text (unicode) strings in both Python 2 and 3 (rather than bytes in Python 2 and text in Python 3, the default situation for unmarked string literals.) Otherwise running `makemigrations` under Python 3 will generate spurious new migrations to convert all these string attributes to text.

The easiest way to achieve this is to follow the advice in Django’s *Python 3 porting guide* and make sure that all your modules begin with `from __future__ import unicode_literals`, so that all unmarked string literals are always unicode, regardless of Python version. When you add this to an app with existing migrations generated on Python 2, your next run of `makemigrations` on Python 3 will likely generate many changes as it converts all the bytestring attributes to text strings; this is normal and should only happen once.

### 3.7.13 Supporting multiple Django versions

If you are the maintainer of a third-party app with models, you may need to ship migrations that support multiple Django versions. In this case, you should always run `makemigrations` **with the lowest Django version you wish to support**.

The migrations system will maintain backwards-compatibility according to the same policy as the rest of Django, so migration files generated on Django X.Y should run unchanged on Django X.Y+1. The migrations system does not promise forwards-compatibility, however. New features may be added, and migration files generated with newer versions of Django may not work on older versions.

See also:

*The Migrations Operations Reference* Covers the schema operations API, special operations, and writing your own operations.

*The Writing Migrations “how-to”* Explains how to structure and write database migrations for different scenarios you might encounter.

## 3.8 Managing files

This document describes Django’s file access APIs for files such as those uploaded by a user. The lower level APIs are general enough that you could use them for other purposes. If you want to handle “static files” (JS, CSS, etc.), see *Managing static files* (e.g. *images*, *JavaScript*, *CSS*).

By default, Django stores files locally, using the `MEDIA_ROOT` and `MEDIA_URL` settings. The examples below assume that you’re using these defaults.

However, Django provides ways to write custom *file storage systems* that allow you to completely customize where and how Django stores files. The second half of this document describes how these storage systems work.

### 3.8.1 Using files in models

When you use a `FileField` or `ImageField`, Django provides a set of APIs you can use to deal with that file.

Consider the following model, using an `ImageField` to store a photo:

```
from django.db import models

class Car(models.Model):
    name = models.CharField(max_length=255)
```

```
price = models.DecimalField(max_digits=5, decimal_places=2)
photo = models.ImageField(upload_to='cars')
```

Any `Car` instance will have a `photo` attribute that you can use to get at the details of the attached photo:

```
>>> car = Car.objects.get(name="57 Chevy")
>>> car.photo
<ImageFieldFile: chevy.jpg>
>>> car.photo.name
'cars/chevy.jpg'
>>> car.photo.path
'/media/cars/chevy.jpg'
>>> car.photo.url
'http://media.example.com/cars/chevy.jpg'
```

This object – `car.photo` in the example – is a `File` object, which means it has all the methods and attributes described below.

---

**Note:** The file is saved as part of saving the model in the database, so the actual file name used on disk cannot be relied on until after the model has been saved.

---

For example, you can change the file name by setting the file’s `name` to a path relative to the file storage’s location (`MEDIA_ROOT` if you are using the default `FileSystemStorage`):

```
>>> import os
>>> from django.conf import settings
>>> initial_path = car.photo.path
>>> car.photo.name = 'cars/chevy_ii.jpg'
>>> new_path = settings.MEDIA_ROOT + car.photo.name
>>> # Move the file on the filesystem
>>> os.rename(initial_path, new_path)
>>> car.save()
>>> car.photo.path
'/media/cars/chevy_ii.jpg'
>>> car.photo.path == new_path
True
```

### 3.8.2 The File object

Internally, Django uses a `django.core.files.File` instance any time it needs to represent a file.

Most of the time you’ll simply use a `File` that Django’s given you (i.e. a file attached to a model as above, or perhaps an uploaded file).

If you need to construct a `File` yourself, the easiest way is to create one using a Python built-in `file` object:

```
>>> from django.core.files import File

# Create a Python file object using open()
>>> f = open('/path/to/hello.world', 'w')
>>> myfile = File(f)
```

Now you can use any of the documented attributes and methods of the `File` class.

Be aware that files created in this way are not automatically closed. The following approach may be used to close files automatically:

```
>>> from django.core.files import File

# Create a Python file object using open() and the with statement
>>> with open('/path/to/hello.world', 'w') as f:
...     myfile = File(f)
...     myfile.write('Hello World')
...
>>> myfile.closed
True
>>> f.closed
True
```

Closing files is especially important when accessing file fields in a loop over a large number of objects. If files are not manually closed after accessing them, the risk of running out of file descriptors may arise. This may lead to the following error:

```
IOError: [Errno 24] Too many open files
```

### 3.8.3 File storage

Behind the scenes, Django delegates decisions about how and where to store files to a file storage system. This is the object that actually understands things like file systems, opening and reading files, etc.

Django's default file storage is given by the `DEFAULT_FILE_STORAGE` setting; if you don't explicitly provide a storage system, this is the one that will be used.

See below for details of the built-in default file storage system, and see *Writing a custom storage system* for information on writing your own file storage system.

#### Storage objects

Though most of the time you'll want to use a `File` object (which delegates to the proper storage for that file), you can use file storage systems directly. You can create an instance of some custom file storage class, or – often more useful – you can use the global default storage system:

```
>>> from django.core.files.storage import default_storage
>>> from django.core.files.base import ContentFile

>>> path = default_storage.save('/path/to/file', ContentFile('new content'))
>>> path
'/path/to/file'

>>> default_storage.size(path)
11
>>> default_storage.open(path).read()
'new content'

>>> default_storage.delete(path)
>>> default_storage.exists(path)
False
```

See *File storage API* for the file storage API.

## The built-in filesystem storage class

Django ships with a `django.core.files.storage.FileSystemStorage` class which implements basic local filesystem file storage.

For example, the following code will store uploaded files under `/media/photos` regardless of what your `MEDIA_ROOT` setting is:

```
from django.db import models
from django.core.files.storage import FileSystemStorage

fs = FileSystemStorage(location='/media/photos')

class Car(models.Model):
    ...
    photo = models.ImageField(storage=fs)
```

*Custom storage systems* work the same way: you can pass them in as the `storage` argument to a `FileField`.

## 3.9 Testing in Django

Automated testing is an extremely useful bug-killing tool for the modern Web developer. You can use a collection of tests – a **test suite** – to solve, or avoid, a number of problems:

- When you're writing new code, you can use tests to validate your code works as expected.
- When you're refactoring or modifying old code, you can use tests to ensure your changes haven't affected your application's behavior unexpectedly.

Testing a Web application is a complex task, because a Web application is made of several layers of logic – from HTTP-level request handling, to form validation and processing, to template rendering. With Django's test-execution framework and assorted utilities, you can simulate requests, insert test data, inspect your application's output and generally verify your code is doing what it should be doing.

The best part is, it's really easy.

The preferred way to write tests in Django is using the `unittest` module built in to the Python standard library. This is covered in detail in the *Writing and running tests* document.

You can also use any *other* Python test framework; Django provides an API and tools for that kind of integration. They are described in the *Using different testing frameworks* section of *Advanced testing topics*.

### 3.9.1 Writing and running tests

#### See also:

The *testing tutorial*, the *testing tools reference*, and the *advanced testing topics*.

This document is split into two primary sections. First, we explain how to write tests with Django. Then, we explain how to run them.

#### Writing tests

Django's unit tests use a Python standard library module: `unittest`. This module defines tests using a class-based approach.

Here is an example which subclasses from `django.test.TestCase`, which is a subclass of `unittest.TestCase` that runs each test inside a transaction to provide isolation:

```
from django.test import TestCase
from myapp.models import Animal

class AnimalTestCase(TestCase):
    def setUp(self):
        Animal.objects.create(name="lion", sound="roar")
        Animal.objects.create(name="cat", sound="meow")

    def test_animals_can_speak(self):
        """Animals that can speak are correctly identified"""
        lion = Animal.objects.get(name="lion")
        cat = Animal.objects.get(name="cat")
        self.assertEqual(lion.speak(), 'The lion says "roar"')
        self.assertEqual(cat.speak(), 'The cat says "meow"')
```

When you *run your tests*, the default behavior of the test utility is to find all the test cases (that is, subclasses of `unittest.TestCase`) in any file whose name begins with `test`, automatically build a test suite out of those test cases, and run that suite.

For more details about `unittest`, see the Python documentation.

---

### Where should the tests live?

The default `startapp` template creates a `tests.py` file in the new application. This might be fine if you only have a few tests, but as your test suite grows you'll likely want to restructure it into a `tests` package so you can split your tests into different submodules such as `test_models.py`, `test_views.py`, `test_forms.py`, etc. Feel free to pick whatever organizational scheme you like.

See also *Using the Django test runner to test reusable applications*.

**Warning:** If your tests rely on database access such as creating or querying models, be sure to create your test classes as subclasses of `django.test.TestCase` rather than `unittest.TestCase`.

Using `unittest.TestCase` avoids the cost of running each test in a transaction and flushing the database, but if your tests interact with the database their behavior will vary based on the order that the test runner executes them. This can lead to unit tests that pass when run in isolation but fail when run in a suite.

## Running tests

Once you've written tests, run them using the `test` command of your project's `manage.py` utility:

```
$ ./manage.py test
```

Test discovery is based on the `unittest` module's [built-in test discovery](#). By default, this will discover tests in any file named `test*.py` under the current working directory.

You can specify particular tests to run by supplying any number of "test labels" to `./manage.py test`. Each test label can be a full Python dotted path to a package, module, `TestCase` subclass, or test method. For instance:

```
# Run all the tests in the animals.tests module
$ ./manage.py test animals.tests
```

```
# Run all the tests found within the 'animals' package
$ ./manage.py test animals

# Run just one test case
$ ./manage.py test animals.tests.AnimalTestCase

# Run just one test method
$ ./manage.py test animals.tests.AnimalTestCase.test_animals_can_speak
```

You can also provide a path to a directory to discover tests below that directory:

```
$ ./manage.py test animals/
```

You can specify a custom filename pattern match using the `-p` (or `--pattern`) option, if your test files are named differently from the `test*.py` pattern:

```
$ ./manage.py test --pattern="tests_*.py"
```

If you press `Ctrl-C` while the tests are running, the test runner will wait for the currently running test to complete and then exit gracefully. During a graceful exit the test runner will output details of any test failures, report on how many tests were run and how many errors and failures were encountered, and destroy any test databases as usual. Thus pressing `Ctrl-C` can be very useful if you forget to pass the `--failfast` option, notice that some tests are unexpectedly failing and want to get details on the failures without waiting for the full test run to complete.

If you do not want to wait for the currently running test to finish, you can press `Ctrl-C` a second time and the test run will halt immediately, but not gracefully. No details of the tests run before the interruption will be reported, and any test databases created by the run will not be destroyed.

---

### Test with warnings enabled

It's a good idea to run your tests with Python warnings enabled: `python -Wall manage.py test`. The `-Wall` flag tells Python to display deprecation warnings. Django, like many other Python libraries, uses these warnings to flag when features are going away. It also might flag areas in your code that aren't strictly wrong but could benefit from a better implementation.

---

### The test database

Tests that require a database (namely, model tests) will not use your “real” (production) database. Separate, blank databases are created for the tests.

Regardless of whether the tests pass or fail, the test databases are destroyed when all the tests have been executed.

You can prevent the test databases from being destroyed by using the `test --keepdb` option. This will preserve the test database between runs. If the database does not exist, it will first be created. Any migrations will also be applied in order to keep it up to date.

The default test database names are created by prepending `test_` to the value of each `NAME` in `DATABASES`. When using SQLite, the tests will use an in-memory database by default (i.e., the database will be created in memory, bypassing the filesystem entirely!). The `TEST` dictionary in `DATABASES` offers a number of settings to configure your test database. For example, if you want to use a different database name, specify `NAME` in the `TEST` dictionary for any given database in `DATABASES`.

On PostgreSQL, `USER` will also need read access to the built-in `postgres` database.

Aside from using a separate database, the test runner will otherwise use all of the same database settings you have in your settings file: `ENGINE`, `USER`, `HOST`, etc. The test database is created by the user specified by `USER`, so you'll need to make sure that the given user account has sufficient privileges to create a new database on the system.

For fine-grained control over the character encoding of your test database, use the `CHARSET TEST` option. If you're using MySQL, you can also use the `COLLATION` option to control the particular collation used by the test database. See the [settings documentation](#) for details of these and other advanced settings.

If using an SQLite in-memory database with Python 3.4+ and SQLite 3.7.13+, `shared cache` will be enabled, so you can write tests with ability to share the database between threads.

---

### Finding data from your production database when running tests?

If your code attempts to access the database when its modules are compiled, this will occur *before* the test database is set up, with potentially unexpected results. For example, if you have a database query in module-level code and a real database exists, production data could pollute your tests. *It is a bad idea to have such import-time database queries in your code* anyway - rewrite your code so that it doesn't do this.

This also applies to customized implementations of `ready()`.

---

#### See also:

The [advanced multi-db testing topics](#).

### Order in which tests are executed

In order to guarantee that all `TestCase` code starts with a clean database, the Django test runner reorders tests in the following way:

- All `TestCase` subclasses are run first.
- Then, all other Django-based tests (test cases based on `SimpleTestCase`, including `TransactionTestCase`) are run with no particular ordering guaranteed nor enforced among them.
- Then any other `unittest.TestCase` tests (including doctests) that may alter the database without restoring it to its original state are run.

---

**Note:** The new ordering of tests may reveal unexpected dependencies on test case ordering. This is the case with doctests that relied on state left in the database by a given `TransactionTestCase` test, they must be updated to be able to run independently.

---

You may reverse the execution order inside groups using the `test --reverse` option. This can help with ensuring your tests are independent from each other.

### Rollback emulation

Any initial data loaded in migrations will only be available in `TestCase` tests and not in `TransactionTestCase` tests, and additionally only on backends where transactions are supported (the most important exception being MySQL/ISAM). This is also true for tests which rely on `TransactionTestCase` such as `LiveServerTestCase` and `StaticLiveServerTestCase`.

Django can reload that data for you on a per-testcase basis by setting the `serialized_rollback` option to `True` in the body of the `TestCase` or `TransactionTestCase`, but note that this will slow down that test suite by approximately 3x.

Third-party apps or those developing against MyISAM will need to set this; in general, however, you should be developing your own projects against a transactional database and be using `TestCase` for most tests, and thus not need this setting.

The initial serialization is usually very quick, but if you wish to exclude some apps from this process (and speed up test runs slightly), you may add those apps to `TEST_NON_SERIALIZED_APPS`.

To prevent serialized data from being loaded twice, setting `serialized_rollback=True` disables the `post_migrate` signal when flushing the test database.

## Other test conditions

Regardless of the value of the `DEBUG` setting in your configuration file, all Django tests run with `DEBUG=False`. This is to ensure that the observed output of your code matches what will be seen in a production setting.

Caches are not cleared after each test, and running “`manage.py test fooapp`” can insert data from the tests into the cache of a live system if you run your tests in production because, unlike databases, a separate “test cache” is not used. This behavior [may change](#) in the future.

## Understanding the test output

When you run your tests, you’ll see a number of messages as the test runner prepares itself. You can control the level of detail of these messages with the `verbosity` option on the command line:

```
Creating test database...
Creating table myapp_animal
Creating table myapp_mineral
```

This tells you that the test runner is creating a test database, as described in the previous section.

Once the test database has been created, Django will run your tests. If everything goes well, you’ll see something like this:

```
-----
Ran 22 tests in 0.221s
OK
```

If there are test failures, however, you’ll see full details about which tests failed:

```
=====
FAIL: test_was_published_recently_with_future_poll (polls.tests.PollMethodTests)
-----
Traceback (most recent call last):
  File "/dev/mysite/polls/tests.py", line 16, in test_was_published_recently_with_
↪future_poll
    self.assertIs(future_poll.was_published_recently(), False)
AssertionError: True is not False
-----
Ran 1 test in 0.003s
FAILED (failures=1)
```

A full explanation of this error output is beyond the scope of this document, but it’s pretty intuitive. You can consult the documentation of Python’s `unittest` library for details.

Note that the return code for the test-runner script is 1 for any number of failed and erroneous tests. If all the tests pass, the return code is 0. This feature is useful if you're using the test-runner script in a shell script and need to test for success or failure at that level.

## Speeding up the tests

### Running tests in parallel

As long as your tests are properly isolated, you can run them in parallel to gain a speed up on multi-core hardware. See `test --parallel`.

### Password hashing

The default password hasher is rather slow by design. If you're authenticating many users in your tests, you may want to use a custom settings file and set the `PASSWORD_HASHERS` setting to a faster hashing algorithm:

```
PASSWORD_HASHERS = [  
    'django.contrib.auth.hashers.MD5PasswordHasher',  
]
```

Don't forget to also include in `PASSWORD_HASHERS` any hashing algorithm used in fixtures, if any.

## 3.9.2 Testing tools

Django provides a small set of tools that come in handy when writing tests.

### The test client

The test client is a Python class that acts as a dummy Web browser, allowing you to test your views and interact with your Django-powered application programmatically.

Some of the things you can do with the test client are:

- Simulate GET and POST requests on a URL and observe the response – everything from low-level HTTP (result headers and status codes) to page content.
- See the chain of redirects (if any) and check the URL and status code at each step.
- Test that a given request is rendered by a given Django template, with a template context that contains certain values.

Note that the test client is not intended to be a replacement for [Selenium](#) or other “in-browser” frameworks. Django's test client has a different focus. In short:

- Use Django's test client to establish that the correct template is being rendered and that the template is passed the correct context data.
- Use in-browser frameworks like [Selenium](#) to test *rendered* HTML and the *behavior* of Web pages, namely JavaScript functionality. Django also provides special support for those frameworks; see the section on `LiveServerTestCase` for more details.

A comprehensive test suite should use a combination of both test types.

## Overview and a quick example

To use the test client, instantiate `django.test.Client` and retrieve Web pages:

```
>>> from django.test import Client
>>> c = Client()
>>> response = c.post('/login/', {'username': 'john', 'password': 'smith'})
>>> response.status_code
200
>>> response = c.get('/customer/details/')
>>> response.content
b'<!DOCTYPE html...'
```

As this example suggests, you can instantiate `Client` from within a session of the Python interactive interpreter.

Note a few important things about how the test client works:

- The test client does *not* require the Web server to be running. In fact, it will run just fine with no Web server running at all! That's because it avoids the overhead of HTTP and deals directly with the Django framework. This helps make the unit tests run quickly.
- When retrieving pages, remember to specify the *path* of the URL, not the whole domain. For example, this is correct:

```
>>> c.get('/login/')
```

This is incorrect:

```
>>> c.get('https://www.example.com/login/')
```

The test client is not capable of retrieving Web pages that are not powered by your Django project. If you need to retrieve other Web pages, use a Python standard library module such as `urllib`.

- To resolve URLs, the test client uses whatever URLconf is pointed-to by your `ROOT_URLCONF` setting.
- Although the above example would work in the Python interactive interpreter, some of the test client's functionality, notably the template-related functionality, is only available *while tests are running*.

The reason for this is that Django's test runner performs a bit of black magic in order to determine which template was loaded by a given view. This black magic (essentially a patching of Django's template system in memory) only happens during test running.

- By default, the test client will disable any CSRF checks performed by your site.

If, for some reason, you *want* the test client to perform CSRF checks, you can create an instance of the test client that enforces CSRF checks. To do this, pass in the `enforce_csrf_checks` argument when you construct your client:

```
>>> from django.test import Client
>>> csrf_client = Client(enforce_csrf_checks=True)
```

## Making requests

Use the `django.test.Client` class to make requests.

**class `Client`** (`enforce_csrf_checks=False`, *\*\*defaults*)

It requires no arguments at time of construction. However, you can use keywords arguments to specify some default headers. For example, this will send a `User-Agent` HTTP header in each request:

```
>>> c = Client(HTTP_USER_AGENT='Mozilla/5.0')
```

The values from the `extra` keywords arguments passed to `get()`, `post()`, etc. have precedence over the defaults passed to the class constructor.

The `enforce_csrf_checks` argument can be used to test CSRF protection (see above).

Once you have a `Client` instance, you can call any of the following methods:

**get** (*path*, *data=None*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a GET request on the provided `path` and returns a `Response` object, which is documented below.

The key-value pairs in the `data` dictionary are used to create a GET data payload. For example:

```
>>> c = Client()
>>> c.get('/customers/details/', {'name': 'fred', 'age': 7})
```

...will result in the evaluation of a GET request equivalent to:

```
/customers/details/?name=fred&age=7
```

The `extra` keyword arguments parameter can be used to specify headers to be sent in the request. For example:

```
>>> c = Client()
>>> c.get('/customers/details/', {'name': 'fred', 'age': 7},
...      HTTP_X_REQUESTED_WITH='XMLHttpRequest')
```

...will send the HTTP header `HTTP_X_REQUESTED_WITH` to the details view, which is a good way to test code paths that use the `django.http.HttpRequest.is_ajax()` method.

---

### CGI specification

The headers sent via `**extra` should follow CGI specification. For example, emulating a different “Host” header as sent in the HTTP request from the browser to the server should be passed as `HTTP_HOST`.

If you already have the GET arguments in URL-encoded form, you can use that encoding instead of using the `data` argument. For example, the previous GET request could also be posed as:

```
>>> c = Client()
>>> c.get('/customers/details/?name=fred&age=7')
```

If you provide a URL with both an encoded GET data and a `data` argument, the `data` argument will take precedence.

If you set `follow` to `True` the client will follow any redirects and a `redirect_chain` attribute will be set in the response object containing tuples of the intermediate urls and status codes.

If you had a URL `/redirect_me/` that redirected to `/next/`, that redirected to `/final/`, this is what you’d see:

```
>>> response = c.get('/redirect_me/', follow=True)
>>> response.redirect_chain
[('http://testserver/next/', 302), ('http://testserver/final/', 302)]
```

If you set `secure` to `True` the client will emulate an HTTPS request.

**post** (*path*, *data=None*, *content\_type=MULTIPART\_CONTENT*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a POST request on the provided *path* and returns a *Response* object, which is documented below.

The key-value pairs in the *data* dictionary are used to submit POST data. For example:

```
>>> c = Client()
>>> c.post('/login/', {'name': 'fred', 'passwd': 'secret'})
```

...will result in the evaluation of a POST request to this URL:

```
/login/
```

...with this POST data:

```
name=fred&passwd=secret
```

If you provide *content\_type* (e.g. *text/xml* for an XML payload), the contents of *data* will be sent as-is in the POST request, using *content\_type* in the HTTP *Content-Type* header.

If you don't provide a value for *content\_type*, the values in *data* will be transmitted with a content type of *multipart/form-data*. In this case, the key-value pairs in *data* will be encoded as a multipart message and used to create the POST data payload.

To submit multiple values for a given key – for example, to specify the selections for a `<select multiple>` – provide the values as a list or tuple for the required key. For example, this value of *data* would submit three selected values for the field named *choices*:

```
{'choices': ('a', 'b', 'd')}
```

Submitting files is a special case. To POST a file, you need only provide the file field name as a key, and a file handle to the file you wish to upload as a value. For example:

```
>>> c = Client()
>>> with open('wishlist.doc') as fp:
...     c.post('/customers/wishes/', {'name': 'fred', 'attachment': fp})
```

(The name *attachment* here is not relevant; use whatever name your file-processing code expects.)

You may also provide any file-like object (e.g., *StringIO* or *BytesIO*) as a file handle.

Note that if you wish to use the same file handle for multiple *post()* calls then you will need to manually reset the file pointer between posts. The easiest way to do this is to manually close the file after it has been provided to *post()*, as demonstrated above.

You should also ensure that the file is opened in a way that allows the data to be read. If your file contains binary data such as an image, this means you will need to open the file in *rb* (read binary) mode.

The *extra* argument acts the same as for *Client.get()*.

If the URL you request with a POST contains encoded parameters, these parameters will be made available in the request.GET data. For example, if you were to make the request:

```
>>> c.post('/login/?visitor=true', {'name': 'fred', 'passwd': 'secret'})
```

... the view handling this request could interrogate *request.POST* to retrieve the username and password, and could interrogate *request.GET* to determine if the user was a visitor.

If you set *follow* to *True* the client will follow any redirects and a *redirect\_chain* attribute will be set in the response object containing tuples of the intermediate urls and status codes.

If you set `secure` to `True` the client will emulate an HTTPS request.

**head** (*path*, *data=None*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a HEAD request on the provided `path` and returns a `Response` object. This method works just like `Client.get()`, including the `follow`, `secure` and `extra` arguments, except it does not return a message body.

**options** (*path*, *data=''*, *content\_type='application/octet-stream'*, *follow=False*, *secure=False*, *\*\*extra*)

Makes an OPTIONS request on the provided `path` and returns a `Response` object. Useful for testing RESTful interfaces.

When `data` is provided, it is used as the request body, and a `Content-Type` header is set to `content_type`.

The `follow`, `secure` and `extra` arguments act the same as for `Client.get()`.

**put** (*path*, *data=''*, *content\_type='application/octet-stream'*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a PUT request on the provided `path` and returns a `Response` object. Useful for testing RESTful interfaces.

When `data` is provided, it is used as the request body, and a `Content-Type` header is set to `content_type`.

The `follow`, `secure` and `extra` arguments act the same as for `Client.get()`.

**patch** (*path*, *data=''*, *content\_type='application/octet-stream'*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a PATCH request on the provided `path` and returns a `Response` object. Useful for testing RESTful interfaces.

The `follow`, `secure` and `extra` arguments act the same as for `Client.get()`.

**delete** (*path*, *data=''*, *content\_type='application/octet-stream'*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a DELETE request on the provided `path` and returns a `Response` object. Useful for testing RESTful interfaces.

When `data` is provided, it is used as the request body, and a `Content-Type` header is set to `content_type`.

The `follow`, `secure` and `extra` arguments act the same as for `Client.get()`.

**trace** (*path*, *follow=False*, *secure=False*, *\*\*extra*)

Makes a TRACE request on the provided `path` and returns a `Response` object. Useful for simulating diagnostic probes.

Unlike the other request methods, `data` is not provided as a keyword parameter in order to comply with [RFC 7231#section-4.3.8](#), which mandates that TRACE requests must not have a body.

The `follow`, `secure`, and `extra` arguments act the same as for `Client.get()`.

**login** (*\*\*credentials*)

If your site uses Django's [authentication system](#) and you deal with logging in users, you can use the test client's `login()` method to simulate the effect of a user logging into the site.

After you call this method, the test client will have all the cookies and session data required to pass any login-based tests that may form part of a view.

The format of the `credentials` argument depends on which [authentication backend](#) you're using (which is configured by your `AUTHENTICATION_BACKENDS` setting). If you're using the standard authentication backend provided by Django (`ModelBackend`), `credentials` should be the user's username and password, provided as keyword arguments:

```
>>> c = Client()
>>> c.login(username='fred', password='secret')

# Now you can access a view that's only available to logged-in users.
```

If you're using a different authentication backend, this method may require different credentials. It requires whichever credentials are required by your backend's `authenticate()` method.

`login()` returns `True` if the credentials were accepted and login was successful.

Finally, you'll need to remember to create user accounts before you can use this method. As we explained above, the test runner is executed using a test database, which contains no users by default. As a result, user accounts that are valid on your production site will not work under test conditions. You'll need to create users as part of the test suite – either manually (using the Django model API) or with a test fixture. Remember that if you want your test user to have a password, you can't set the user's password by setting the password attribute directly – you must use the `set_password()` function to store a correctly hashed password. Alternatively, you can use the `create_user()` helper method to create a new user with a correctly hashed password.

In previous versions, inactive users (`is_active=False`) were not permitted to login.

#### **force\_login** (*user*, *backend=None*)

If your site uses Django's *authentication system*, you can use the `force_login()` method to simulate the effect of a user logging into the site. Use this method instead of `login()` when a test requires a user be logged in and the details of how a user logged in aren't important.

Unlike `login()`, this method skips the authentication and verification steps: inactive users (`is_active=False`) are permitted to login and the user's credentials don't need to be provided.

The user will have its `backend` attribute set to the value of the `backend` argument (which should be a dotted Python path string), or to `settings.AUTHENTICATION_BACKENDS[0]` if a value isn't provided. The `authenticate()` function called by `login()` normally annotates the user like this.

This method is faster than `login()` since the expensive password hashing algorithms are bypassed. Also, you can speed up `login()` by *using a weaker hasher while testing*.

#### **logout** ()

If your site uses Django's *authentication system*, the `logout()` method can be used to simulate the effect of a user logging out of your site.

After you call this method, the test client will have all the cookies and session data cleared to defaults. Subsequent requests will appear to come from an *AnonymousUser*.

## Testing responses

The `get()` and `post()` methods both return a `Response` object. This `Response` object is *not* the same as the `HttpResponse` object returned by Django views; the test response object has some additional data useful for test code to verify.

Specifically, a `Response` object has the following attributes:

#### **class Response**

##### **client**

The test client that was used to make the request that resulted in the response.

**content**

The body of the response, as a bytestring. This is the final page content as rendered by the view, or any error message.

**context**

The template `Context` instance that was used to render the template that produced the response content.

If the rendered page used multiple templates, then `context` will be a list of `Context` objects, in the order in which they were rendered.

Regardless of the number of templates used during rendering, you can retrieve context values using the `[]` operator. For example, the context variable `name` could be retrieved using:

```
>>> response = client.get('/foo/')
>>> response.context['name']
'Arthur'
```

---

**Not using Django templates?**

This attribute is only populated when using the *DjangoTemplates* backend. If you're using another template engine, *context\_data* may be a suitable alternative on responses with that attribute.

---

**json (\*\*kwargs)**

The body of the response, parsed as JSON. Extra keyword arguments are passed to `json.loads()`. For example:

```
>>> response = client.get('/foo/')
>>> response.json()['name']
'Arthur'
```

If the `Content-Type` header is not `"application/json"`, then a `ValueError` will be raised when trying to parse the response.

**request**

The request data that stimulated the response.

**wsgi\_request**

The `WSGIRequest` instance generated by the test handler that generated the response.

**status\_code**

The HTTP status of the response, as an integer. For a full list of defined codes, see the [IANA status code registry](#).

**templates**

A list of `Template` instances used to render the final content, in the order they were rendered. For each template in the list, use `template.name` to get the template's file name, if the template was loaded from a file. (The name is a string such as `'admin/index.html'`.)

---

**Not using Django templates?**

This attribute is only populated when using the *DjangoTemplates* backend. If you're using another template engine, *template\_name* may be a suitable alternative if you only need the name of the template used for rendering.

---

**resolver\_match**

An instance of *ResolverMatch* for the response. You can use the *func* attribute, for example, to verify the view that served the response:

```
# my_view here is a function based view
self.assertEqual(response.resolver_match.func, my_view)

# class-based views need to be compared by name, as the functions
# generated by as_view() won't be equal
self.assertEqual(response.resolver_match.func.__name__, MyView.as_view().__
↳name__)
```

If the given URL is not found, accessing this attribute will raise a *Resolver404* exception.

You can also use dictionary syntax on the response object to query the value of any settings in the HTTP headers. For example, you could determine the content type of a response using `response['Content-Type']`.

## Exceptions

If you point the test client at a view that raises an exception, that exception will be visible in the test case. You can then use a standard `try ... except` block or `assertRaises()` to test for exceptions.

The only exceptions that are not visible to the test client are *Http404*, *PermissionDenied*, *SystemExit*, and *SuspiciousOperation*. Django catches these exceptions internally and converts them into the appropriate HTTP response codes. In these cases, you can check `response.status_code` in your test.

## Persistent state

The test client is stateful. If a response returns a cookie, then that cookie will be stored in the test client and sent with all subsequent `get()` and `post()` requests.

Expiration policies for these cookies are not followed. If you want a cookie to expire, either delete it manually or create a new `Client` instance (which will effectively delete all cookies).

A test client has two attributes that store persistent state information. You can access these properties as part of a test condition.

### `Client.cookies`

A Python `SimpleCookie` object, containing the current values of all the client cookies. See the documentation of the `http.cookies` module for more.

### `Client.session`

A dictionary-like object containing session information. See the *session documentation* for full details.

To modify the session and then save it, it must be stored in a variable first (because a new `SessionStore` is created every time this property is accessed):

```
def test_something(self):
    session = self.client.session
    session['somekey'] = 'test'
    session.save()
```

## Setting the language

When testing applications that support internationalization and localization, you might want to set the language for a test client request. The method for doing so depends on whether or not the *LocaleMiddleware* is enabled.

If the middleware is enabled, the language can be set by creating a cookie with a name of `LANGUAGE_COOKIE_NAME` and a value of the language code:

```

from django.conf import settings

def test_language_using_cookie(self):
    self.client.cookies.load({settings.LANGUAGE_COOKIE_NAME: 'fr'})
    response = self.client.get('/')
    self.assertEqual(response.content, b"Bienvenue sur mon site.")

```

or by including the `Accept-Language` HTTP header in the request:

```

def test_language_using_header(self):
    response = self.client.get('/', HTTP_ACCEPT_LANGUAGE='fr')
    self.assertEqual(response.content, b"Bienvenue sur mon site.")

```

More details are in *How Django discovers language preference*.

If the middleware isn't enabled, the active language may be set using `translation.override()`:

```

from django.utils import translation

def test_language_using_override(self):
    with translation.override('fr'):
        response = self.client.get('/')
    self.assertEqual(response.content, b"Bienvenue sur mon site.")

```

More details are in *Explicitly setting the active language*.

## Example

The following is a simple unit test using the test client:

```

import unittest
from django.test import Client

class SimpleTest(unittest.TestCase):
    def setUp(self):
        # Every test needs a client.
        self.client = Client()

    def test_details(self):
        # Issue a GET request.
        response = self.client.get('/customer/details/')

        # Check that the response is 200 OK.
        self.assertEqual(response.status_code, 200)

        # Check that the rendered context contains 5 customers.
        self.assertEqual(len(response.context['customers']), 5)

```

`django.test.RequestFactory`

## Provided test case classes

Normal Python unit test classes extend a base class of `unittest.TestCase`. Django provides a few extensions of this base class:

Fig. 3.1: Hierarchy of Django unit testing classes

Converting a normal `unittest.TestCase` to any of the subclasses is easy: change the base class of your test from `unittest.TestCase` to the subclass. All of the standard Python unit test functionality will be available, and it will be augmented with some useful additions as described in each section below.

### SimpleTestCase

#### class SimpleTestCase

A subclass of `unittest.TestCase` that adds this functionality:

- Some useful assertions like:
  - Checking that a callable *raises a certain exception*.
  - Testing form field *rendering and error treatment*.
  - Testing *HTML responses for the presence/lack of a given fragment*.
  - Verifying that a *template has/hasn't been used to generate a given response content*.
  - Verifying a *HTTP redirect* is performed by the app.
  - Robustly testing two *HTML fragments* for equality/inequality or *containment*.
  - Robustly testing two *XML fragments* for equality/inequality.
  - Robustly testing two *JSON fragments* for equality.
- The ability to run tests with *modified settings*.
- Using the *client Client*.

If your tests make any database queries, use subclasses `TransactionTestCase` or `TestCase`.

### SimpleTestCase.allow\_database\_queries

`SimpleTestCase` disallows database queries by default. This helps to avoid executing write queries which will affect other tests since each `SimpleTestCase` test isn't run in a transaction. If you aren't concerned about this problem, you can disable this behavior by setting the `allow_database_queries` class attribute to `True` on your test class.

**Warning:** `SimpleTestCase` and its subclasses (e.g. `TestCase`, ...) rely on `setUpClass()` and `tearDownClass()` to perform some class-wide initialization (e.g. overriding settings). If you need to override those methods, don't forget to call the super implementation:

```
class MyTestCase(TestCase):

    @classmethod
    def setUpClass(cls):
        super(MyTestCase, cls).setUpClass()
        ...

    @classmethod
    def tearDownClass(cls):
        ...
        super(MyTestCase, cls).tearDownClass()
```

Be sure to account for Python's behavior if an exception is raised during `setUpClass()`. If that happens, neither the tests in the class nor `tearDownClass()` are run. In the case of `django.test.TestCase`, this will leak the transaction created in `super()` which results in various symptoms including a segmentation fault on some platforms (reported on OS X). If you want to intentionally raise an exception such as `unittest.SkipTest` in `setUpClass()`, be sure to do it before calling `super()` to avoid this.

### TransactionTestCase

#### class TransactionTestCase

`TransactionTestCase` inherits from `SimpleTestCase` to add some database-specific features:

- Resetting the database to a known state at the beginning of each test to ease testing and using the ORM.
- Database *fixtures*.
- Test *skipping based on database backend features*.
- The remaining specialized `assert*` methods.

Django's `TestCase` class is a more commonly used subclass of `TransactionTestCase` that makes use of database transaction facilities to speed up the process of resetting the database to a known state at the beginning of each test. A consequence of this, however, is that some database behaviors cannot be tested within a Django `TestCase` class. For instance, you cannot test that a block of code is executing within a transaction, as is required when using `select_for_update()`. In those cases, you should use `TransactionTestCase`.

`TransactionTestCase` and `TestCase` are identical except for the manner in which the database is reset to a known state and the ability for test code to test the effects of commit and rollback:

- A `TransactionTestCase` resets the database after the test runs by truncating all tables. A `TransactionTestCase` may call commit and rollback and observe the effects of these calls on the database.
- A `TestCase`, on the other hand, does not truncate tables after a test. Instead, it encloses the test code in a database transaction that is rolled back at the end of the test. This guarantees that the rollback at the end of the test restores the database to its initial state.

**Warning:** `TestCase` running on a database that does not support rollback (e.g. MySQL with the MyISAM storage engine), and all instances of `TransactionTestCase`, will roll back at the end of the test by deleting all data from the test database.

Apps *will not see their data reloaded*; if you need this functionality (for example, third-party apps should enable this) you can set `serialized_rollback = True` inside the `TestCase` body.

## TestCase

### class TestCase

This is the most common class to use for writing tests in Django. It inherits from `TransactionTestCase` (and by extension `SimpleTestCase`). If your Django application doesn't use a database, use `SimpleTestCase`.

The class:

- Wraps the tests within two nested `atomic()` blocks: one for the whole class and one for each test. Therefore, if you want to test some specific database transaction behavior, use `TransactionTestCase`.
- Checks deferrable database constraints at the end of each test.

The check for deferrable database constraints at the end of each test was added.

It also provides an additional method:

#### classmethod TestCase.setUpTestData()

The class-level `atomic` block described above allows the creation of initial data at the class level, once for the whole `TestCase`. This technique allows for faster tests as compared to using `setUp()`.

For example:

```
from django.test import TestCase

class MyTests(TestCase):
    @classmethod
    def setUpTestData(cls):
        # Set up data for the whole TestCase
        cls.foo = Foo.objects.create(bar="Test")
        ...

    def test1(self):
        # Some test using self.foo
        ...

    def test2(self):
        # Some other test using self.foo
        ...
```

Note that if the tests are run on a database with no transaction support (for instance, MySQL with the MyISAM engine), `setUpTestData()` will be called before each test, negating the speed benefits.

Be careful not to modify any objects created in `setUpTestData()` in your test methods. Modifications to in-memory objects from setup work done at the class level will persist between test methods. If you do need to modify them, you could reload them in the `setUp()` method with `refresh_from_db()`, for example.

## LiveServerTestCase

### class LiveServerTestCase

`LiveServerTestCase` does basically the same as `TransactionTestCase` with one extra feature: it launches a live Django server in the background on setup, and shuts it down on teardown. This allows the use of automated test clients other than the *Django dummy client* such as, for example, the `Selenium` client, to execute a series of functional tests inside a browser and simulate a real user’s actions.

By default the live server listens on `localhost` and picks the first available port in the 8081–8179 range. Its full URL can be accessed with `self.live_server_url` during the tests.

In earlier versions, the live server’s default address was always `'localhost:8081'`.

If you’d like to select another address, you may pass a different one using the `test --liveserver` option, for example:

```
$ ./manage.py test --liveserver=localhost:8082
```

In older versions `live_server_url` could only be accessed from an instance. It now is a class property and can be accessed from class methods like `setUpClass()`.

Another way of changing the default server address is by setting the `DJANGO_LIVE_TEST_SERVER_ADDRESS` environment variable somewhere in your code (for example, in a *custom test runner*):

```
import os
os.environ['DJANGO_LIVE_TEST_SERVER_ADDRESS'] = 'localhost:8082'
```

In the case where the tests are run by multiple processes in parallel (for example, in the context of several simultaneous `continuous integration` builds), the processes will compete for the same address, and therefore your tests might randomly fail with an “Address already in use” error. To avoid this problem, you can pass a comma-separated list of ports or ranges of ports (at least as many as the number of potential parallel processes). For example:

```
$ ./manage.py test --liveserver=localhost:8082,8090-8100,9000-9200,7041
```

Then, during test execution, each new live test server will try every specified port until it finds one that is free and takes it.

To demonstrate how to use `LiveServerTestCase`, let’s write a simple `Selenium` test. First of all, you need to install the `selenium` package into your Python path:

```
$ pip install selenium
```

Then, add a `LiveServerTestCase`-based test to your app’s tests module (for example: `myapp/tests.py`). For this example, we’ll assume you’re using the `staticfiles` app and want to have static files served during the execution of your tests similar to what we get at development time with `DEBUG=True`, i.e. without having to collect them using `collectstatic`. We’ll use the `StaticLiveServerTestCase` subclass which provides that functionality. Replace it with `django.test.LiveServerTestCase` if you don’t need that.

The code for this test may look as follows:

```
from django.contrib.staticfiles.testing import StaticLiveServerTestCase
from selenium.webdriver.firefox.webdriver import WebDriver

class MySeleniumTests(StaticLiveServerTestCase):
    fixtures = ['user-data.json']

    @classmethod
    def setUpClass(cls):
```

```
super(MySeleniumTests, cls).setUpClass()
cls.selenium = WebDriver()
cls.selenium.implicitly_wait(10)

@classmethod
def tearDownClass(cls):
    cls.selenium.quit()
    super(MySeleniumTests, cls).tearDownClass()

def test_login(self):
    self.selenium.get('%s%s' % (self.live_server_url, '/login/'))
    username_input = self.selenium.find_element_by_name("username")
    username_input.send_keys('myuser')
    password_input = self.selenium.find_element_by_name("password")
    password_input.send_keys('secret')
    self.selenium.find_element_by_xpath('//*[@value="Log in"]').click()
```

Finally, you may run the test as follows:

```
$ ./manage.py test myapp.tests.MySeleniumTests.test_login
```

This example will automatically open Firefox then go to the login page, enter the credentials and press the “Log in” button. Selenium offers other drivers in case you do not have Firefox installed or wish to use another browser. The example above is just a tiny fraction of what the Selenium client can do; check out the [full reference](#) for more details.

---

**Note:** When using an in-memory SQLite database to run the tests, the same database connection will be shared by two threads in parallel: the thread in which the live server is run and the thread in which the test case is run. It’s important to prevent simultaneous database queries via this shared connection by the two threads, as that may sometimes randomly cause the tests to fail. So you need to ensure that the two threads don’t access the database at the same time. In particular, this means that in some cases (for example, just after clicking a link or submitting a form), you might need to check that a response is received by Selenium and that the next page is loaded before proceeding with further test execution. Do this, for example, by making Selenium wait until the `<body>` HTML tag is found in the response (requires Selenium > 2.13):

```
def test_login(self):
    from selenium.webdriver.support.wait import WebDriverWait
    timeout = 2
    ...
    self.selenium.find_element_by_xpath('//*[@value="Log in"]').click()
    # Wait until the response is received
    WebDriverWait(self.selenium, timeout).until(
        lambda driver: driver.find_element_by_tag_name('body'))
```

The tricky thing here is that there’s really no such thing as a “page load,” especially in modern Web apps that generate HTML dynamically after the server generates the initial document. So, simply checking for the presence of `<body>` in the response might not necessarily be appropriate for all use cases. Please refer to the [Selenium FAQ](#) and [Selenium documentation](#) for more information.

---

## Test cases features

### Default test client

`SimpleTestCase.client`

Every test case in a `django.test.TestCase` instance has access to an instance of a Django test client. This client can be accessed as `self.client`. This client is recreated for each test, so you don't have to worry about state (such as cookies) carrying over from one test to another.

This means, instead of instantiating a `Client` in each test:

```
import unittest
from django.test import Client

class SimpleTest(unittest.TestCase):
    def test_details(self):
        client = Client()
        response = client.get('/customer/details/')
        self.assertEqual(response.status_code, 200)

    def test_index(self):
        client = Client()
        response = client.get('/customer/index/')
        self.assertEqual(response.status_code, 200)
```

...you can just refer to `self.client`, like so:

```
from django.test import TestCase

class SimpleTest(TestCase):
    def test_details(self):
        response = self.client.get('/customer/details/')
        self.assertEqual(response.status_code, 200)

    def test_index(self):
        response = self.client.get('/customer/index/')
        self.assertEqual(response.status_code, 200)
```

## Customizing the test client

`SimpleTestCase.client_class`

If you want to use a different `Client` class (for example, a subclass with customized behavior), use the `client_class` class attribute:

```
from django.test import TestCase, Client

class MyTestClient(Client):
    # Specialized methods for your environment
    ...

class MyTest(TestCase):
    client_class = MyTestClient

    def test_my_stuff(self):
        # Here self.client is an instance of MyTestClient...
        call_some_test_code()
```

## Fixture loading

`TransactionTestCase.fixtures`

A test case for a database-backed website isn't much use if there isn't any data in the database. Tests are more readable and it's more maintainable to create objects using the ORM, for example in `TestCase.setUpTestData()`, however, you can also use fixtures.

A fixture is a collection of data that Django knows how to import into a database. For example, if your site has user accounts, you might set up a fixture of fake user accounts in order to populate your database during tests.

The most straightforward way of creating a fixture is to use the `manage.py dumpdata` command. This assumes you already have some data in your database. See the [dumpdata documentation](#) for more details.

Once you've created a fixture and placed it in a `fixtures` directory in one of your `INSTALLED_APPS`, you can use it in your unit tests by specifying a `fixtures` class attribute on your `django.test.TestCase` subclass:

```
from django.test import TestCase
from myapp.models import Animal

class AnimalTestCase(TestCase):
    fixtures = ['mammals.json', 'birds']

    def setUp(self):
        # Test definitions as before.
        call_setup_methods()

    def testFluffyAnimals(self):
        # A test that uses the fixtures.
        call_some_test_code()
```

Here's specifically what will happen:

- At the start of each test, before `setUp()` is run, Django will flush the database, returning the database to the state it was in directly after `migrate` was called.
- Then, all the named fixtures are installed. In this example, Django will install any JSON fixture named `mammals`, followed by any fixture named `birds`. See the [loaddata](#) documentation for more details on defining and installing fixtures.

For performance reasons, `TestCase` loads fixtures once for the entire test class, before `setUpTestData()`, instead of before each test, and it uses transactions to clean the database before each test. In any case, you can be certain that the outcome of a test will not be affected by another test or by the order of test execution.

By default, fixtures are only loaded into the `default` database. If you are using multiple databases and set `multi_db=True`, fixtures will be loaded into all databases.

## URLconf configuration

If your application provides views, you may want to include tests that use the test client to exercise those views. However, an end user is free to deploy the views in your application at any URL of their choosing. This means that your tests can't rely upon the fact that your views will be available at a particular URL. Decorate your test class or test method with `@override_settings(ROOT_URLCONF=...)` for URLconf configuration.

## Multi-database support

`TransactionTestCase.multi_db`

Django sets up a test database corresponding to every database that is defined in the `DATABASES` definition in your settings file. However, a big part of the time taken to run a Django `TestCase` is consumed by the call to `flush` that ensures that you have a clean database at the start of each test run. If you have multiple databases, multiple flushes are

required (one for each database), which can be a time consuming activity – especially if your tests don't need to test multi-database activity.

As an optimization, Django only flushes the `default` database at the start of each test run. If your setup contains multiple databases, and you have a test that requires every database to be clean, you can use the `multi_db` attribute on the test suite to request a full flush.

For example:

```
class TestMyViews(TestCase):
    multi_db = True

    def test_index_page_view(self):
        call_some_test_code()
```

This test case will flush *all* the test databases before running `test_index_page_view`.

The `multi_db` flag also affects into which databases the `TransactionTestCase.fixtures` are loaded. By default (when `multi_db=False`), fixtures are only loaded into the `default` database. If `multi_db=True`, fixtures are loaded into all databases.

## Overriding settings

**Warning:** Use the functions below to temporarily alter the value of settings in tests. Don't manipulate `django.conf.settings` directly as Django won't restore the original values after such manipulations.

`SimpleTestCase.settings()`

For testing purposes it's often useful to change a setting temporarily and revert to the original value after running the testing code. For this use case Django provides a standard Python context manager (see [PEP 343](#)) called `settings()`, which can be used like this:

```
from django.test import TestCase

class LoginTestCase(TestCase):

    def test_login(self):

        # First check for the default behavior
        response = self.client.get('/sekrit/')
        self.assertRedirects(response, '/accounts/login/?next=/sekrit/')

        # Then override the LOGIN_URL setting
        with self.settings(LOGIN_URL='/other/login/'):
            response = self.client.get('/sekrit/')
            self.assertRedirects(response, '/other/login/?next=/sekrit/')
```

This example will override the `LOGIN_URL` setting for the code in the `with` block and reset its value to the previous state afterwards.

`SimpleTestCase.modify_settings()`

It can prove unwieldy to redefine settings that contain a list of values. In practice, adding or removing values is often sufficient. The `modify_settings()` context manager makes it easy:

```
from django.test import TestCase

class MiddlewareTestCase(TestCase):

    def test_cache_middleware(self):
        with self.modify_settings(MIDDLEWARE={
            'append': 'django.middleware.cache.FetchFromCacheMiddleware',
            'prepend': 'django.middleware.cache.UpdateCacheMiddleware',
            'remove': [
                'django.contrib.sessions.middleware.SessionMiddleware',
                'django.contrib.auth.middleware.AuthenticationMiddleware',
                'django.contrib.messages.middleware.MessageMiddleware',
            ],
        }):
            response = self.client.get('/')
            # ...
```

For each action, you can supply either a list of values or a string. When the value already exists in the list, append and prepend have no effect; neither does remove when the value doesn't exist.

### `override_settings()`

In case you want to override a setting for a test method, Django provides the `override_settings()` decorator (see [PEP 318](#)). It's used like this:

```
from django.test import TestCase, override_settings

class LoginTestCase(TestCase):

    @override_settings(LOGIN_URL='/other/login/')
    def test_login(self):
        response = self.client.get('/sekrit/')
        self.assertRedirects(response, '/other/login/?next=/sekrit/')
```

The decorator can also be applied to `TestCase` classes:

```
from django.test import TestCase, override_settings

@override_settings(LOGIN_URL='/other/login/')
class LoginTestCase(TestCase):

    def test_login(self):
        response = self.client.get('/sekrit/')
        self.assertRedirects(response, '/other/login/?next=/sekrit/')
```

### `modify_settings()`

Likewise, Django provides the `modify_settings()` decorator:

```
from django.test import TestCase, modify_settings

class MiddlewareTestCase(TestCase):

    @modify_settings(MIDDLEWARE={
        'append': 'django.middleware.cache.FetchFromCacheMiddleware',
        'prepend': 'django.middleware.cache.UpdateCacheMiddleware',
    })
    def test_cache_middleware(self):
```

```
response = self.client.get('/')
# ...
```

The decorator can also be applied to test case classes:

```
from django.test import TestCase, modify_settings

@modify_settings(MIDDLEWARE={
    'append': 'django.middleware.cache.FetchFromCacheMiddleware',
    'prepend': 'django.middleware.cache.UpdateCacheMiddleware',
})
class MiddlewareTestCase(TestCase):

    def test_cache_middleware(self):
        response = self.client.get('/')
        # ...
```

**Note:** When given a class, these decorators modify the class directly and return it; they don't create and return a modified copy of it. So if you try to tweak the above examples to assign the return value to a different name than `LoginTestCase` or `MiddlewareTestCase`, you may be surprised to find that the original test case classes are still equally affected by the decorator. For a given class, `modify_settings()` is always applied after `override_settings()`.

**Warning:** The settings file contains some settings that are only consulted during initialization of Django internals. If you change them with `override_settings`, the setting is changed if you access it via the `django.conf.settings` module, however, Django's internals access it differently. Effectively, using `override_settings()` or `modify_settings()` with these settings is probably not going to do what you expect it to do.

We do not recommend altering the `DATABASES` setting. Altering the `CACHES` setting is possible, but a bit tricky if you are using internals that make use of caching, like `django.contrib.sessions`. For example, you will have to reinitialize the session backend in a test that uses cached sessions and overrides `CACHES`.

Finally, avoid aliasing your settings as module-level constants as `override_settings()` won't work on such values since they are only evaluated the first time the module is imported.

You can also simulate the absence of a setting by deleting it after settings have been overridden, like this:

```
@override_settings()
def test_something(self):
    del settings.LOGIN_URL
    ...
```

When overriding settings, make sure to handle the cases in which your app's code uses a cache or similar feature that retains state even if the setting is changed. Django provides the `django.test.signals.setting_changed` signal that lets you register callbacks to clean up and otherwise reset state when settings are changed.

Django itself uses this signal to reset various data:

Overridden settings	Data reset
USE_TZ, TIME_ZONE	Databases timezone
TEMPLATES	Template engines
SERIALIZATION_MODULES	Serializers cache
LOCALE_PATHS, LANGUAGE_CODE	Default translation and loaded translations
MEDIA_ROOT, DEFAULT_FILE_STORAGE	Default file storage

## Emptying the test mailbox

If you use any of Django's custom `TestCase` classes, the test runner will clear the contents of the test email mailbox at the start of each test case.

For more detail on email services during tests, see *Email services* below.

## Assertions

As Python's normal `unittest.TestCase` class implements assertion methods such as `assertTrue()` and `assertEqual()`, Django's custom `TestCase` class provides a number of custom assertion methods that are useful for testing Web applications:

The failure messages given by most of these assertion methods can be customized with the `msg_prefix` argument. This string will be prefixed to any failure message generated by the assertion. This allows you to provide additional details that may help you to identify the location and cause of a failure in your test suite.

`SimpleTestCase.assertRaisesMessage` (*expected\_exception*, *expected\_message*, *callable*, *\*args*, *\*\*kwargs*)

`SimpleTestCase.assertRaisesMessage` (*expected\_exception*, *expected\_message*)

Asserts that execution of `callable` raises `expected_exception` and that `expected_message` is found in the exception's message. Any other outcome is reported as a failure. It's a simpler version of `unittest.TestCase.assertRaisesRegex()` with the difference that `expected_message` isn't treated as a regular expression.

If only the `expected_exception` and `expected_message` parameters are given, returns a context manager so that the code being tested can be written inline rather than as a function:

```
with self.assertRaisesMessage(ValueError, 'invalid literal for int()'):
    int('a')
```

Deprecated since version 1.9: Passing `callable` as a keyword argument called `callable_obj` is deprecated. Pass the callable as a positional argument instead.

`SimpleTestCase.assertFieldOutput` (*fieldclass*, *valid*, *invalid*, *field\_args=None*, *field\_kwargs=None*, *empty\_value=''*)

Asserts that a form field behaves correctly with various inputs.

### Parameters

- **fieldclass** – the class of the field to be tested.
- **valid** – a dictionary mapping valid inputs to their expected cleaned values.
- **invalid** – a dictionary mapping invalid inputs to one or more raised error messages.
- **field\_args** – the args passed to instantiate the field.
- **field\_kwargs** – the kwargs passed to instantiate the field.
- **empty\_value** – the expected clean output for inputs in `empty_values`.

For example, the following code tests that an `EmailField` accepts `a@a.com` as a valid email address, but rejects `aaa` with a reasonable error message:

```
self.assertFieldOutput(EmailField, {'a@a.com': 'a@a.com'}, {'aaa': ['Enter a_
↳valid email address.']})
```

`SimpleTestCase.assertFormError` (*response, form, field, errors, msg\_prefix=''*)

Asserts that a field on a form raises the provided list of errors when rendered on the form.

`form` is the name the `Form` instance was given in the template context.

`field` is the name of the field on the form to check. If `field` has a value of `None`, non-field errors (errors you can access via `form.non_field_errors()`) will be checked.

`errors` is an error string, or a list of error strings, that are expected as a result of form validation.

`SimpleTestCase.assertFormsetError` (*response, formset, form\_index, field, errors, msg\_prefix=''*)

Asserts that the `formset` raises the provided list of errors when rendered.

`formset` is the name the `Formset` instance was given in the template context.

`form_index` is the number of the form within the `Formset`. If `form_index` has a value of `None`, non-form errors (errors you can access via `formset.non_form_errors()`) will be checked.

`field` is the name of the field on the form to check. If `field` has a value of `None`, non-field errors (errors you can access via `form.non_field_errors()`) will be checked.

`errors` is an error string, or a list of error strings, that are expected as a result of form validation.

`SimpleTestCase.assertContains` (*response, text, count=None, status\_code=200, msg\_prefix='', html=False*)

Asserts that a `Response` instance produced the given `status_code` and that `text` appears in the content of the response. If `count` is provided, `text` must occur exactly `count` times in the response.

Set `html` to `True` to handle `text` as HTML. The comparison with the response content will be based on HTML semantics instead of character-by-character equality. Whitespace is ignored in most cases, attribute ordering is not significant. See `assertHTMLEqual()` for more details.

`SimpleTestCase.assertNotContains` (*response, text, status\_code=200, msg\_prefix='', html=False*)

Asserts that a `Response` instance produced the given `status_code` and that `text` does *not* appear in the content of the response.

Set `html` to `True` to handle `text` as HTML. The comparison with the response content will be based on HTML semantics instead of character-by-character equality. Whitespace is ignored in most cases, attribute ordering is not significant. See `assertHTMLEqual()` for more details.

`SimpleTestCase.assertTemplateUsed` (*response, template\_name, msg\_prefix='', count=None*)

Asserts that the template with the given name was used in rendering the response.

The name is a string such as `'admin/index.html'`.

The count argument is an integer indicating the number of times the template should be rendered. Default is `None`, meaning that the template should be rendered one or more times.

You can use this as a context manager, like this:

```
with self.assertTemplateUsed('index.html'):
    render_to_string('index.html')
with self.assertTemplateUsed(template_name='index.html'):
    render_to_string('index.html')
```

`SimpleTestCase.assertTemplateNotUsed` (*response, template\_name, msg\_prefix=''*)

Asserts that the template with the given name was *not* used in rendering the response.

You can use this as a context manager in the same way as `assertTemplateUsed()`.

```
SimpleTestCase.assertRedirects (response, expected_url, status_code=302,
                                target_status_code=200, msg_prefix='',
                                fetch_redirect_response=True)
```

Asserts that the response returned a `status_code` redirect status, redirected to `expected_url` (including any GET data), and that the final page was received with `target_status_code`.

If your request used the `follow` argument, the `expected_url` and `target_status_code` will be the url and status code for the final point of the redirect chain.

If `fetch_redirect_response` is `False`, the final page won't be loaded. Since the test client can't fetch external URLs, this is particularly useful if `expected_url` isn't part of your Django app.

Scheme is handled correctly when making comparisons between two URLs. If there isn't any scheme specified in the location where we are redirected to, the original request's scheme is used. If present, the scheme in `expected_url` is the one used to make the comparisons to.

Deprecated since version 1.9: The `host` argument is deprecated, as redirections are no longer forced to be absolute URLs.

```
SimpleTestCase.assertHTMLEqual (html1, html2, msg=None)
```

Asserts that the strings `html1` and `html2` are equal. The comparison is based on HTML semantics. The comparison takes following things into account:

- Whitespace before and after HTML tags is ignored.
- All types of whitespace are considered equivalent.
- All open tags are closed implicitly, e.g. when a surrounding tag is closed or the HTML document ends.
- Empty tags are equivalent to their self-closing version.
- The ordering of attributes of an HTML element is not significant.
- Attributes without an argument are equal to attributes that equal in name and value (see the examples).

The following examples are valid tests and don't raise any `AssertionError`:

```
self.assertHTMLEqual(
    '<p>Hello <b>world!</p>',
    '''<p>
    Hello <b>world! <b/>
    </p>'''
)
self.assertHTMLEqual(
    '<input type="checkbox" checked="checked" id="id_accept_terms" />',
    '<input id="id_accept_terms" type="checkbox" checked>'
)
```

`html1` and `html2` must be valid HTML. An `AssertionError` will be raised if one of them cannot be parsed.

Output in case of error can be customized with the `msg` argument.

```
SimpleTestCase.assertHTMLNotEqual (html1, html2, msg=None)
```

Asserts that the strings `html1` and `html2` are *not* equal. The comparison is based on HTML semantics. See `assertHTMLEqual()` for details.

`html1` and `html2` must be valid HTML. An `AssertionError` will be raised if one of them cannot be parsed.

Output in case of error can be customized with the `msg` argument.

`SimpleTestCase.assertXMLEqual(xml1, xml2, msg=None)`

Asserts that the strings `xml1` and `xml2` are equal. The comparison is based on XML semantics. Similarly to `assertHTMLEqual()`, the comparison is made on parsed content, hence only semantic differences are considered, not syntax differences. When invalid XML is passed in any parameter, an `AssertionError` is always raised, even if both string are identical.

Output in case of error can be customized with the `msg` argument.

`SimpleTestCase.assertXMLNotEqual(xml1, xml2, msg=None)`

Asserts that the strings `xml1` and `xml2` are *not* equal. The comparison is based on XML semantics. See `assertXMLEqual()` for details.

Output in case of error can be customized with the `msg` argument.

`SimpleTestCase.assertInHTML(needle, haystack, count=None, msg_prefix='')`

Asserts that the HTML fragment `needle` is contained in the `haystack` one.

If the `count` integer argument is specified, then additionally the number of `needle` occurrences will be strictly verified.

Whitespace in most cases is ignored, and attribute ordering is not significant. The passed-in arguments must be valid HTML.

`SimpleTestCase.assertJSONEqual(raw, expected_data, msg=None)`

Asserts that the JSON fragments `raw` and `expected_data` are equal. Usual JSON non-significant whitespace rules apply as the heavyweight is delegated to the `json` library.

Output in case of error can be customized with the `msg` argument.

`SimpleTestCase.assertJSONNotEqual(raw, expected_data, msg=None)`

Asserts that the JSON fragments `raw` and `expected_data` are *not* equal. See `assertJSONEqual()` for further details.

Output in case of error can be customized with the `msg` argument.

`TransactionTestCase.assertQuerysetEqual(qs, values, transform=repr, ordered=True, msg=None)`

Asserts that a queryset `qs` returns a particular list of values `values`.

The comparison of the contents of `qs` and `values` is performed using the function `transform`; by default, this means that the `repr()` of each value is compared. Any other callable can be used if `repr()` doesn't provide a unique or helpful comparison.

By default, the comparison is also ordering dependent. If `qs` doesn't provide an implicit ordering, you can set the `ordered` parameter to `False`, which turns the comparison into a `collections.Counter` comparison. If the order is undefined (if the given `qs` isn't ordered and the comparison is against more than one ordered values), a `ValueError` is raised.

Output in case of error can be customized with the `msg` argument.

`TransactionTestCase.assertNumQueries(num, func, *args, **kwargs)`

Asserts that when `func` is called with `*args` and `**kwargs` that `num` database queries are executed.

If a "using" key is present in `kwargs` it is used as the database alias for which to check the number of queries. If you wish to call a function with a `using` parameter you can do it by wrapping the call with a `lambda` to add an extra parameter:

```
self.assertNumQueries(7, lambda: my_function(using=7))
```

You can also use this as a context manager:

```
with self.assertNumQueries(2):
    Person.objects.create(name="Aaron")
    Person.objects.create(name="Daniel")
```

## Tagging tests

You can tag your tests so you can easily run a particular subset. For example, you might label fast or slow tests:

```
from django.test import tag

class SampleTestCase(TestCase):

    @tag('fast')
    def test_fast(self):
        ...

    @tag('slow')
    def test_slow(self):
        ...

    @tag('slow', 'core')
    def test_slow_but_core(self):
        ...
```

You can also tag a test case:

```
@tag('slow', 'core')
class SampleTestCase(TestCase):
    ...
```

Then you can choose which tests to run. For example, to run only fast tests:

```
$ ./manage.py test --tag=fast
```

Or to run fast tests and the core one (even though it's slow):

```
$ ./manage.py test --tag=fast --tag=core
```

You can also exclude tests by tag. To run core tests if they are not slow:

```
$ ./manage.py test --tag=core --exclude-tag=slow
```

`test --exclude-tag` has precedence over `test --tag`, so if a test has two tags and you select one of them and exclude the other, the test won't be run.

## Email services

If any of your Django views send email using *Django's email functionality*, you probably don't want to send email each time you run a test using that view. For this reason, Django's test runner automatically redirects all Django-sent email to a dummy outbox. This lets you test every aspect of sending email – from the number of messages sent to the contents of each message – without actually sending the messages.

The test runner accomplishes this by transparently replacing the normal email backend with a testing backend. (Don't worry – this has no effect on any other email senders outside of Django, such as your machine's mail server, if you're running one.)

`django.core.mail.outbox`

During test running, each outgoing email is saved in `django.core.mail.outbox`. This is a simple list of all `EmailMessage` instances that have been sent. The `outbox` attribute is a special attribute that is created *only* when the `locmem` email backend is used. It doesn't normally exist as part of the `django.core.mail` module and you can't import it directly. The code below shows how to access this attribute correctly.

Here's an example test that examines `django.core.mail.outbox` for length and contents:

```
from django.core import mail
from django.test import TestCase

class EmailTest(TestCase):
    def test_send_email(self):
        # Send message.
        mail.send_mail(
            'Subject here', 'Here is the message.',
            'from@example.com', ['to@example.com'],
            fail_silently=False,
        )

        # Test that one message has been sent.
        self.assertEqual(len(mail.outbox), 1)

        # Verify that the subject of the first message is correct.
        self.assertEqual(mail.outbox[0].subject, 'Subject here')
```

As noted *previously*, the test `outbox` is emptied at the start of every test in a Django `*TestCase`. To empty the `outbox` manually, assign the empty list to `mail.outbox`:

```
from django.core import mail

# Empty the test outbox
mail.outbox = []
```

## Management Commands

Management commands can be tested with the `call_command()` function. The output can be redirected into a `StringIO` instance:

```
from django.core.management import call_command
from django.test import TestCase
from django.utils.six import StringIO

class ClosepollTest(TestCase):
    def test_command_output(self):
        out = StringIO()
        call_command('closepoll', stdout=out)
        self.assertIn('Expected output', out.getvalue())
```

## Skipping tests

The `unittest` library provides the `@skipIf` and `@skipUnless` decorators to allow you to skip tests if you know ahead of time that those tests are going to fail under certain conditions.

For example, if your test requires a particular optional library in order to succeed, you could decorate the test case with `@skipIf`. Then, the test runner will report that the test wasn't executed and why, instead of failing the test or omitting the test altogether.

To supplement these test skipping behaviors, Django provides two additional skip decorators. Instead of testing a generic boolean, these decorators check the capabilities of the database, and skip the test if the database doesn't support a specific named feature.

The decorators use a string identifier to describe database features. This string corresponds to attributes of the database connection features class. See `django.db.backends.BaseDatabaseFeatures` class for a full list of database features that can be used as a basis for skipping tests.

**skipIfDBFeature** (*\*feature\_name\_strings*)

Skip the decorated test or `TestCase` if all of the named database features are supported.

For example, the following test will not be executed if the database supports transactions (e.g., it would *not* run under PostgreSQL, but it would under MySQL with MyISAM tables):

```
class MyTests(TestCase):
    @skipIfDBFeature('supports_transactions')
    def test_transaction_behavior(self):
        # ... conditional test code
        pass
```

**skipUnlessDBFeature** (*\*feature\_name\_strings*)

Skip the decorated test or `TestCase` if any of the named database features are *not* supported.

For example, the following test will only be executed if the database supports transactions (e.g., it would run under PostgreSQL, but *not* under MySQL with MyISAM tables):

```
class MyTests(TestCase):
    @skipUnlessDBFeature('supports_transactions')
    def test_transaction_behavior(self):
        # ... conditional test code
        pass
```

### 3.9.3 Advanced testing topics

#### The request factory

##### class RequestFactory

The `RequestFactory` shares the same API as the test client. However, instead of behaving like a browser, the `RequestFactory` provides a way to generate a request instance that can be used as the first argument to any view. This means you can test a view function the same way as you would test any other function – as a black box, with exactly known inputs, testing for specific outputs.

The API for the `RequestFactory` is a slightly restricted subset of the test client API:

- It only has access to the HTTP methods `get()`, `post()`, `put()`, `delete()`, `head()`, `options()`, and `trace()`.
- These methods accept all the same arguments *except* for `follows`. Since this is just a factory for producing requests, it's up to you to handle the response.
- It does not support middleware. Session and authentication attributes must be supplied by the test itself if required for the view to function properly.

## Example

The following is a simple unit test using the request factory:

```

from django.contrib.auth.models import AnonymousUser, User
from django.test import TestCase, RequestFactory

from .views import MyView, my_view

class SimpleTest(TestCase):
    def setUp(self):
        # Every test needs access to the request factory.
        self.factory = RequestFactory()
        self.user = User.objects.create_user(
            username='jacob', email='jacob@...', password='top_secret')

    def test_details(self):
        # Create an instance of a GET request.
        request = self.factory.get('/customer/details')

        # Recall that middleware are not supported. You can simulate a
        # logged-in user by setting request.user manually.
        request.user = self.user

        # Or you can simulate an anonymous user by setting request.user to
        # an AnonymousUser instance.
        request.user = AnonymousUser()

        # Test my_view() as if it were deployed at /customer/details
        response = my_view(request)
        # Use this syntax for class-based views.
        response = MyView.as_view()(request)
        self.assertEqual(response.status_code, 200)

```

## Tests and multiple databases

### Testing primary/replica configurations

If you're testing a multiple database configuration with primary/replica (referred to as master/slave by some databases) replication, this strategy of creating test databases poses a problem. When the test databases are created, there won't be any replication, and as a result, data created on the primary won't be seen on the replica.

To compensate for this, Django allows you to define that a database is a *test mirror*. Consider the following (simplified) example database configuration:

```

DATABASES = {
    'default': {
        'ENGINE': 'django.db.backends.mysql',
        'NAME': 'myproject',
        'HOST': 'dbprimary',
        # ... plus some other settings
    },
    'replica': {
        'ENGINE': 'django.db.backends.mysql',
        'NAME': 'myproject',
        'HOST': 'dbreplica',
    }
}

```

```
    'TEST': {
        'MIRROR': 'default',
    },
    # ... plus some other settings
}
```

In this setup, we have two database servers: `dbprimary`, described by the database alias `default`, and `dbreplica` described by the alias `replica`. As you might expect, `dbreplica` has been configured by the database administrator as a read replica of `dbprimary`, so in normal activity, any write to `default` will appear on `replica`.

If Django created two independent test databases, this would break any tests that expected replication to occur. However, the `replica` database has been configured as a test mirror (using the `MIRROR` test setting), indicating that under testing, `replica` should be treated as a mirror of `default`.

When the test environment is configured, a test version of `replica` will *not* be created. Instead the connection to `replica` will be redirected to point at `default`. As a result, writes to `default` will appear on `replica` – but because they are actually the same database, not because there is data replication between the two databases.

### Controlling creation order for test databases

By default, Django will assume all databases depend on the `default` database and therefore always create the `default` database first. However, no guarantees are made on the creation order of any other databases in your test setup.

If your database configuration requires a specific creation order, you can specify the dependencies that exist using the `DEPENDENCIES` test setting. Consider the following (simplified) example database configuration:

```
DATABASES = {
    'default': {
        # ... db settings
        'TEST': {
            'DEPENDENCIES': ['diamonds'],
        },
    },
    'diamonds': {
        # ... db settings
        'TEST': {
            'DEPENDENCIES': [],
        },
    },
    'clubs': {
        # ... db settings
        'TEST': {
            'DEPENDENCIES': ['diamonds'],
        },
    },
    'spades': {
        # ... db settings
        'TEST': {
            'DEPENDENCIES': ['diamonds', 'hearts'],
        },
    },
    'hearts': {
        # ... db settings
        'TEST': {
```

```

        'DEPENDENCIES': ['diamonds', 'clubs'],
    },
}

```

Under this configuration, the `diamonds` database will be created first, as it is the only database alias without dependencies. The default and `clubs` alias will be created next (although the order of creation of this pair is not guaranteed), then `hearts`, and finally `spades`.

If there are any circular dependencies in the `DEPENDENCIES` definition, an `ImproperlyConfigured` exception will be raised.

### Advanced features of `TransactionTestCase`

`TransactionTestCase.available_apps`

**Warning:** This attribute is a private API. It may be changed or removed without a deprecation period in the future, for instance to accommodate changes in application loading.

It's used to optimize Django's own test suite, which contains hundreds of models but no relations between models in different applications.

By default, `available_apps` is set to `None`. After each test, Django calls `flush` to reset the database state. This empties all tables and emits the `post_migrate` signal, which re-creates one content type and three permissions for each model. This operation gets expensive proportionally to the number of models.

Setting `available_apps` to a list of applications instructs Django to behave as if only the models from these applications were available. The behavior of `TransactionTestCase` changes as follows:

- `post_migrate` is fired before each test to create the content types and permissions for each model in available apps, in case they're missing.
- After each test, Django empties only tables corresponding to models in available apps. However, at the database level, truncation may cascade to related models in unavailable apps. Furthermore `post_migrate` isn't fired; it will be fired by the next `TransactionTestCase`, after the correct set of applications is selected.

Since the database isn't fully flushed, if a test creates instances of models not included in `available_apps`, they will leak and they may cause unrelated tests to fail. Be careful with tests that use sessions; the default session engine stores them in the database.

Since `post_migrate` isn't emitted after flushing the database, its state after a `TransactionTestCase` isn't the same as after a `TestCase`: it's missing the rows created by listeners to `post_migrate`. Considering the *order in which tests are executed*, this isn't an issue, provided either all `TransactionTestCase` in a given test suite declare `available_apps`, or none of them.

`available_apps` is mandatory in Django's own test suite.

`TransactionTestCase.reset_sequences`

Setting `reset_sequences = True` on a `TransactionTestCase` will make sure sequences are always reset before the test run:

```

class TestsThatDependsOnPrimaryKeySequences(TransactionTestCase):
    reset_sequences = True

```

```
def test_animal_pk(self):
    lion = Animal.objects.create(name="lion", sound="roar")
    # lion.pk is guaranteed to always be 1
    self.assertEqual(lion.pk, 1)
```

Unless you are explicitly testing primary keys sequence numbers, it is recommended that you do not hard code primary key values in tests.

Using `reset_sequences = True` will slow down the test, since the primary key reset is an relatively expensive database operation.

## Using the Django test runner to test reusable applications

If you are writing a *reusable application* you may want to use the Django test runner to run your own test suite and thus benefit from the Django testing infrastructure.

A common practice is a `tests` directory next to the application code, with the following structure:

```
runtests.py
polls/
  __init__.py
  models.py
  ...
tests/
  __init__.py
  models.py
  test_settings.py
  tests.py
```

Let's take a look inside a couple of those files:

```
runtests.py
#!/usr/bin/env python
import os
import sys

import django
from django.conf import settings
from django.test.utils import get_runner

if __name__ == "__main__":
    os.environ['DJANGO_SETTINGS_MODULE'] = 'tests.test_settings'
    django.setup()
    TestRunner = get_runner(settings)
    test_runner = TestRunner()
    failures = test_runner.run_tests(["tests"])
    sys.exit(bool(failures))
```

This is the script that you invoke to run the test suite. It sets up the Django environment, creates the test database and runs the tests.

For the sake of clarity, this example contains only the bare minimum necessary to use the Django test runner. You may want to add command-line options for controlling verbosity, passing in specific test labels to run, etc.

```
tests/test_settings.py
SECRET_KEY = 'fake-key'
INSTALLED_APPS = [
```

```
"tests",
]
```

This file contains the *Django settings* required to run your app's tests.

Again, this is a minimal example; your tests may require additional settings to run.

Since the *tests* package is included in *INSTALLED\_APPS* when running your tests, you can define test-only models in its `models.py` file.

## Using different testing frameworks

Clearly, `unittest` is not the only Python testing framework. While Django doesn't provide explicit support for alternative frameworks, it does provide a way to invoke tests constructed for an alternative framework as if they were normal Django tests.

When you run `./manage.py test`, Django looks at the *TEST\_RUNNER* setting to determine what to do. By default, *TEST\_RUNNER* points to `'django.test.runner.DiscoverRunner'`. This class defines the default Django testing behavior. This behavior involves:

1. Performing global pre-test setup.
2. Looking for tests in any file below the current directory whose name matches the pattern `test*.py`.
3. Creating the test databases.
4. Running `migrate` to install models and initial data into the test databases.
5. Running the tests that were found.
6. Destroying the test databases.
7. Performing global post-test teardown.

If you define your own test runner class and point *TEST\_RUNNER* at that class, Django will execute your test runner whenever you run `./manage.py test`. In this way, it is possible to use any test framework that can be executed from Python code, or to modify the Django test execution process to satisfy whatever testing requirements you may have.

## Defining a test runner

A test runner is a class defining a `run_tests()` method. Django ships with a `DiscoverRunner` class that defines the default Django testing behavior. This class defines the `run_tests()` entry point, plus a selection of other methods that are used to by `run_tests()` to set up, execute and tear down the test suite.

```
class DiscoverRunner (pattern='test*.py', top_level=None, verbosity=1, interactive=True, failfast=False,  
keepdb=False, reverse=False, debug_sql=False, **kwargs)
```

`DiscoverRunner` will search for tests in any file matching `pattern`.

`top_level` can be used to specify the directory containing your top-level Python modules. Usually Django can figure this out automatically, so it's not necessary to specify this option. If specified, it should generally be the directory containing your `manage.py` file.

`verbosity` determines the amount of notification and debug information that will be printed to the console; 0 is no output, 1 is normal output, and 2 is verbose output.

If `interactive` is `True`, the test suite has permission to ask the user for instructions when the test suite is executed. An example of this behavior would be asking for permission to delete an existing test database. If `interactive` is `False`, the test suite must be able to run without any manual intervention.

If `failfast` is `True`, the test suite will stop running after the first test failure is detected.

If `keepdb` is `True`, the test suite will use the existing database, or create one if necessary. If `False`, a new database will be created, prompting the user to remove the existing one, if present.

If `reverse` is `True`, test cases will be executed in the opposite order. This could be useful to debug tests that aren't properly isolated and have side effects. *Grouping by test class* is preserved when using this option.

If `debug_sql` is `True`, failing test cases will output SQL queries logged to the *django.db.backends logger* as well as the traceback. If `verbosity` is 2, then queries in all tests are output.

Django may, from time to time, extend the capabilities of the test runner by adding new arguments. The `**kwargs` declaration allows for this expansion. If you subclass `DiscoverRunner` or write your own test runner, ensure it accepts `**kwargs`.

Your test runner may also define additional command-line options. Create or override an `add_arguments(cls, parser)` class method and add custom arguments by calling `parser.add_argument()` inside the method, so that the `test` command will be able to use those arguments.

## Attributes

### `DiscoverRunner.test_suite`

The class used to build the test suite. By default it is set to `unittest.TestSuite`. This can be overridden if you wish to implement different logic for collecting tests.

### `DiscoverRunner.test_runner`

This is the class of the low-level test runner which is used to execute the individual tests and format the results. By default it is set to `unittest.TextTestRunner`. Despite the unfortunate similarity in naming conventions, this is not the same type of class as `DiscoverRunner`, which covers a broader set of responsibilities. You can override this attribute to modify the way tests are run and reported.

### `DiscoverRunner.test_loader`

This is the class that loads tests, whether from `TestCases` or modules or otherwise and bundles them into test suites for the runner to execute. By default it is set to `unittest.defaultTestLoader`. You can override this attribute if your tests are going to be loaded in unusual ways.

## Methods

### `DiscoverRunner.run_tests(test_labels, extra_tests=None, **kwargs)`

Run the test suite.

`test_labels` allows you to specify which tests to run and supports several formats (see *DiscoverRunner.build\_suite()* for a list of supported formats).

`extra_tests` is a list of extra `TestCase` instances to add to the suite that is executed by the test runner. These extra tests are run in addition to those discovered in the modules listed in `test_labels`.

This method should return the number of tests that failed.

### `classmethod DiscoverRunner.add_arguments(parser)`

Override this class method to add custom arguments accepted by the `test` management command. See *argparse.ArgumentParser.add\_argument()* for details about adding arguments to a parser.

### `DiscoverRunner.setup_test_environment(**kwargs)`

Sets up the test environment by calling *setup\_test\_environment()* and setting `DEBUG` to `False`.

### `DiscoverRunner.build_suite(test_labels, extra_tests=None, **kwargs)`

Constructs a test suite that matches the test labels provided.

`test_labels` is a list of strings describing the tests to be run. A test label can take one of four forms:

- `path.to.test_module.TestCase.test_method` – Run a single test method in a test case.
- `path.to.test_module.TestCase` – Run all the test methods in a test case.
- `path.to.module` – Search for and run all tests in the named Python package or module.
- `path/to/directory` – Search for and run all tests below the named directory.

If `test_labels` has a value of `None`, the test runner will search for tests in all files below the current directory whose names match its pattern (see above).

`extra_tests` is a list of extra `TestCase` instances to add to the suite that is executed by the test runner. These extra tests are run in addition to those discovered in the modules listed in `test_labels`.

Returns a `TestSuite` instance ready to be run.

`DiscoverRunner.setup_databases (**kwargs)`

Creates the test databases.

Returns a data structure that provides enough detail to undo the changes that have been made. This data will be provided to the `teardown_databases()` function at the conclusion of testing.

`DiscoverRunner.run_suite (suite, **kwargs)`

Runs the test suite.

Returns the result produced by the running the test suite.

`DiscoverRunner.teardown_databases (old_config, **kwargs)`

Destroys the test databases, restoring pre-test conditions.

`old_config` is a data structure defining the changes in the database configuration that need to be reversed. It is the return value of the `setup_databases()` method.

`DiscoverRunner.teardown_test_environment (**kwargs)`

Restores the pre-test environment.

`DiscoverRunner.suite_result (suite, result, **kwargs)`

Computes and returns a return code based on a test suite, and the result from that test suite.

## Testing utilities

### `django.test.utils`

To assist in the creation of your own test runner, Django provides a number of utility methods in the `django.test.utils` module.

`setup_test_environment ()`

Performs global pre-test setup, such as installing instrumentation for the template rendering system and setting up the dummy email outbox.

`teardown_test_environment ()`

Performs global post-test teardown, such as removing instrumentation from the template system and restoring normal email services.

### `django.db.connection.creation`

The creation module of the database backend also provides some utilities that can be useful during testing.

**create\_test\_db** (*verbosity=1, autoclobber=False, serialize=True, keepdb=False*)

Creates a new test database and runs `migrate` against it.

`verbosity` has the same behavior as in `run_tests()`.

`autoclobber` describes the behavior that will occur if a database with the same name as the test database is discovered:

- If `autoclobber` is `False`, the user will be asked to approve destroying the existing database. `sys.exit` is called if the user does not approve.
- If `autoclobber` is `True`, the database will be destroyed without consulting the user.

`serialize` determines if Django serializes the database into an in-memory JSON string before running tests (used to restore the database state between tests if you don't have transactions). You can set this to `False` to speed up creation time if you don't have any test classes with `serialized_rollback=True`.

If you are using the default test runner, you can control this with the the `SERIALIZE` entry in the `TEST` dictionary.

`keepdb` determines if the test run should use an existing database, or create a new one. If `True`, the existing database will be used, or created if not present. If `False`, a new database will be created, prompting the user to remove the existing one, if present.

Returns the name of the test database that it created.

`create_test_db()` has the side effect of modifying the value of `NAME` in `DATABASES` to match the name of the test database.

**destroy\_test\_db** (*old\_database\_name, verbosity=1, keepdb=False*)

Destroys the database whose name is the value of `NAME` in `DATABASES`, and sets `NAME` to the value of `old_database_name`.

The `verbosity` argument has the same behavior as for `DiscoverRunner`.

If the `keepdb` argument is `True`, then the connection to the database will be closed, but the database will not be destroyed.

## Integration with `coverage.py`

Code coverage describes how much source code has been tested. It shows which parts of your code are being exercised by tests and which are not. It's an important part of testing applications, so it's strongly recommended to check the coverage of your tests.

Django can be easily integrated with `coverage.py`, a tool for measuring code coverage of Python programs. First, [install coverage.py](#). Next, run the following from your project folder containing `manage.py`:

```
coverage run --source='.' manage.py test myapp
```

This runs your tests and collects coverage data of the executed files in your project. You can see a report of this data by typing following command:

```
coverage report
```

Note that some Django code was executed while running tests, but it is not listed here because of the `source` flag passed to the previous command.

For more options like annotated HTML listings detailing missed lines, see the [coverage.py docs](#).

## 3.10 User authentication in Django

### 3.10.1 Using the Django authentication system

This document explains the usage of Django's authentication system in its default configuration. This configuration has evolved to serve the most common project needs, handling a reasonably wide range of tasks, and has a careful implementation of passwords and permissions. For projects where authentication needs differ from the default, Django supports extensive *extension and customization* of authentication.

Django authentication provides both authentication and authorization together and is generally referred to as the authentication system, as these features are somewhat coupled.

#### User objects

*User* objects are the core of the authentication system. They typically represent the people interacting with your site and are used to enable things like restricting access, registering user profiles, associating content with creators etc. Only one class of user exists in Django's authentication framework, i.e., '*superusers*' or admin '*staff*' users are just user objects with special attributes set, not different classes of user objects.

The primary attributes of the default user are:

- *username*
- *password*
- *email*
- *first\_name*
- *last\_name*

See the *full API documentation* for full reference, the documentation that follows is more task oriented.

#### Creating users

The most direct way to create users is to use the included *create\_user()* helper function:

```
>>> from django.contrib.auth.models import User
>>> user = User.objects.create_user('john', 'lennon@thebeatles.com', 'johnpassword')

# At this point, user is a User object that has already been saved
# to the database. You can continue to change its attributes
# if you want to change other fields.
>>> user.last_name = 'Lennon'
>>> user.save()
```

If you have the Django admin installed, you can also *create users interactively*.

#### Creating superusers

Create superusers using the *createsuperuser* command:

```
$ python manage.py createsuperuser --username=joe --email=joe@example.com
```

You will be prompted for a password. After you enter one, the user will be created immediately. If you leave off the *--username* or *--email* options, it will prompt you for those values.

## Changing passwords

Django does not store raw (clear text) passwords on the user model, but only a hash (see *documentation of how passwords are managed* for full details). Because of this, do not attempt to manipulate the password attribute of the user directly. This is why a helper function is used when creating a user.

To change a user's password, you have several options:

`manage.py changepassword *username*` offers a method of changing a user's password from the command line. It prompts you to change the password of a given user which you must enter twice. If they both match, the new password will be changed immediately. If you do not supply a user, the command will attempt to change the password whose username matches the current system user.

You can also change a password programmatically, using `set_password()`:

```
>>> from django.contrib.auth.models import User
>>> u = User.objects.get(username='john')
>>> u.set_password('new password')
>>> u.save()
```

If you have the Django admin installed, you can also change user's passwords on the *authentication system's admin pages*.

Django also provides *views* and *forms* that may be used to allow users to change their own passwords.

Changing a user's password will log out all their sessions. See *Session invalidation on password change* for details.

## Authenticating users

### `authenticate(**credentials)`

Use `authenticate()` to verify a set of credentials. It takes credentials as keyword arguments, username and password for the default case, checks them against each *authentication backend*, and returns a *User* object if the credentials are valid for a backend. If the credentials aren't valid for any backend or if a backend raises *PermissionDenied*, it returns None. For example:

```
from django.contrib.auth import authenticate
user = authenticate(username='john', password='secret')
if user is not None:
    # A backend authenticated the credentials
else:
    # No backend authenticated the credentials
```

---

**Note:** This is a low level way to authenticate a set of credentials; for example, it's used by the *RemoteUserMiddleware*. Unless you are writing your own authentication system, you probably won't use this. Rather if you are looking for a way to limit access to logged in users, see the *login\_required()* decorator.

---

## Permissions and Authorization

Django comes with a simple permissions system. It provides a way to assign permissions to specific users and groups of users.

It's used by the Django admin site, but you're welcome to use it in your own code.

The Django admin site uses permissions as follows:

- Access to view the “add” form and add an object is limited to users with the “add” permission for that type of object.
- Access to view the change list, view the “change” form and change an object is limited to users with the “change” permission for that type of object.
- Access to delete an object is limited to users with the “delete” permission for that type of object.

Permissions can be set not only per type of object, but also per specific object instance. By using the `has_add_permission()`, `has_change_permission()` and `has_delete_permission()` methods provided by the `ModelAdmin` class, it is possible to customize permissions for different object instances of the same type.

`User` objects have two many-to-many fields: `groups` and `user_permissions`. `User` objects can access their related objects in the same way as any other *Django model*:

```
myuser.groups.set([group_list])
myuser.groups.add(group, group, ...)
myuser.groups.remove(group, group, ...)
myuser.groups.clear()
myuser.user_permissions.set([permission_list])
myuser.user_permissions.add(permission, permission, ...)
myuser.user_permissions.remove(permission, permission, ...)
myuser.user_permissions.clear()
```

## Default permissions

When `django.contrib.auth` is listed in your `INSTALLED_APPS` setting, it will ensure that three default permissions – add, change and delete – are created for each Django model defined in one of your installed applications.

These permissions will be created when you run `manage.py migrate`; the first time you run `migrate` after adding `django.contrib.auth` to `INSTALLED_APPS`, the default permissions will be created for all previously-installed models, as well as for any new models being installed at that time. Afterward, it will create default permissions for new models each time you run `manage.py migrate` (the function that creates permissions is connected to the `post_migrate` signal).

Assuming you have an application with an `app_label` `foo` and a model named `Bar`, to test for basic permissions you should use:

- add: `user.has_perm('foo.add_bar')`
- change: `user.has_perm('foo.change_bar')`
- delete: `user.has_perm('foo.delete_bar')`

The `Permission` model is rarely accessed directly.

## Groups

`django.contrib.auth.models.Group` models are a generic way of categorizing users so you can apply permissions, or some other label, to those users. A user can belong to any number of groups.

A user in a group automatically has the permissions granted to that group. For example, if the group `Site editors` has the permission `can_edit_home_page`, any user in that group will have that permission.

Beyond permissions, groups are a convenient way to categorize users to give them some label, or extended functionality. For example, you could create a group `'Special users'`, and you could write code that could, say, give them access to a members-only portion of your site, or send them members-only email messages.

## Programmatically creating permissions

While *custom permissions* can be defined within a model's Meta class, you can also create permissions directly. For example, you can create the `can_publish` permission for a `BlogPost` model in `myapp`:

```
from myapp.models import BlogPost
from django.contrib.auth.models import Permission
from django.contrib.contenttypes.models import ContentType

content_type = ContentType.objects.get_for_model(BlogPost)
permission = Permission.objects.create(
    codename='can_publish',
    name='Can Publish Posts',
    content_type=content_type,
)
```

The permission can then be assigned to a *User* via its `user_permissions` attribute or to a *Group* via its `permissions` attribute.

## Permission caching

The *ModelBackend* caches permissions on the user object after the first time they need to be fetched for a permissions check. This is typically fine for the request-response cycle since permissions aren't typically checked immediately after they are added (in the admin, for example). If you are adding permissions and checking them immediately afterward, in a test or view for example, the easiest solution is to re-fetch the user from the database. For example:

```
from django.contrib.auth.models import Permission, User
from django.shortcuts import get_object_or_404

def user_gains_perms(request, user_id):
    user = get_object_or_404(User, pk=user_id)
    # any permission check will cache the current set of permissions
    user.has_perm('myapp.change_bar')

    permission = Permission.objects.get(codename='change_bar')
    user.user_permissions.add(permission)

    # Checking the cached permission set
    user.has_perm('myapp.change_bar') # False

    # Request new instance of User
    # Be aware that user.refresh_from_db() won't clear the cache.
    user = get_object_or_404(User, pk=user_id)

    # Permission cache is repopulated from the database
    user.has_perm('myapp.change_bar') # True

    ...
```

## Authentication in Web requests

Django uses *sessions* and middleware to hook the authentication system into *request objects*.

These provide a `request.user` attribute on every request which represents the current user. If the current user has not logged in, this attribute will be set to an instance of *AnonymousUser*, otherwise it will be an instance of *User*.

You can tell them apart with `is_authenticated`, like so:

```
if request.user.is_authenticated:
    # Do something for authenticated users.
    ...
else:
    # Do something for anonymous users.
    ...
```

## How to log a user in

If you have an authenticated user you want to attach to the current session - this is done with a `login()` function.

**login** (*request*, *user*, *backend=None*)

To log a user in, from a view, use `login()`. It takes an `HttpRequest` object and a `User` object. `login()` saves the user's ID in the session, using Django's session framework.

Note that any data set during the anonymous session is retained in the session after a user logs in.

This example shows how you might use both `authenticate()` and `login()`:

```
from django.contrib.auth import authenticate, login

def my_view(request):
    username = request.POST['username']
    password = request.POST['password']
    user = authenticate(username=username, password=password)
    if user is not None:
        login(request, user)
        # Redirect to a success page.
        ...
    else:
        # Return an 'invalid login' error message.
        ...
```

In older versions, when you're manually logging a user in, you *must* successfully authenticate the user with `authenticate()` before you call `login()`. Now you can set the backend using the new backend argument.

## Selecting the authentication backend

When a user logs in, the user's ID and the backend that was used for authentication are saved in the user's session. This allows the same *authentication backend* to fetch the user's details on a future request. The authentication backend to save in the session is selected as follows:

1. Use the value of the optional `backend` argument, if provided.
2. Use the value of the `user.backend` attribute, if present. This allows pairing `authenticate()` and `login()`: `authenticate()` sets the `user.backend` attribute on the user object it returns.
3. Use the backend in `AUTHENTICATION_BACKENDS`, if there is only one.
4. Otherwise, raise an exception.

In cases 1 and 2, the value of the `backend` argument or the `user.backend` attribute should be a dotted import path string (like that found in `AUTHENTICATION_BACKENDS`), not the actual backend class.

## How to log a user out

### `logout` (*request*)

To log out a user who has been logged in via `django.contrib.auth.login()`, use `django.contrib.auth.logout()` within your view. It takes an `HttpRequest` object and has no return value. Example:

```
from django.contrib.auth import logout

def logout_view(request):
    logout(request)
    # Redirect to a success page.
```

Note that `logout()` doesn't throw any errors if the user wasn't logged in.

When you call `logout()`, the session data for the current request is completely cleaned out. All existing data is removed. This is to prevent another person from using the same Web browser to log in and have access to the previous user's session data. If you want to put anything into the session that will be available to the user immediately after logging out, do that *after* calling `django.contrib.auth.logout()`.

## Limiting access to logged-in users

### The raw way

The simple, raw way to limit access to pages is to check `request.user.is_authenticated` and either redirect to a login page:

```
from django.conf import settings
from django.shortcuts import redirect

def my_view(request):
    if not request.user.is_authenticated:
        return redirect('%s?next=%s' % (settings.LOGIN_URL, request.path))
    # ...
```

...or display an error message:

```
from django.shortcuts import render

def my_view(request):
    if not request.user.is_authenticated:
        return render(request, 'myapp/login_error.html')
    # ...
```

### The `login_required` decorator

#### `login_required` (*redirect\_field\_name='next', login\_url=None*)

As a shortcut, you can use the convenient `login_required()` decorator:

```
from django.contrib.auth.decorators import login_required

@login_required
def my_view(request):
    ...
```

`login_required()` does the following:

- If the user isn't logged in, redirect to `settings.LOGIN_URL`, passing the current absolute path in the query string. Example: `/accounts/login/?next=/polls/3/`.
- If the user is logged in, execute the view normally. The view code is free to assume the user is logged in.

By default, the path that the user should be redirected to upon successful authentication is stored in a query string parameter called "next". If you would prefer to use a different name for this parameter, `login_required()` takes an optional `redirect_field_name` parameter:

```
from django.contrib.auth.decorators import login_required

@login_required(redirect_field_name='my_redirect_field')
def my_view(request):
    ...
```

Note that if you provide a value to `redirect_field_name`, you will most likely need to customize your login template as well, since the template context variable which stores the redirect path will use the value of `redirect_field_name` as its key rather than "next" (the default).

`login_required()` also takes an optional `login_url` parameter. Example:

```
from django.contrib.auth.decorators import login_required

@login_required(login_url='/accounts/login/')
def my_view(request):
    ...
```

Note that if you don't specify the `login_url` parameter, you'll need to ensure that the `settings.LOGIN_URL` and your login view are properly associated. For example, using the defaults, add the following lines to your URLconf:

```
from django.contrib.auth import views as auth_views

url(r'^accounts/login/$', auth_views.login),
```

The `settings.LOGIN_URL` also accepts view function names and *named URL patterns*. This allows you to freely remap your login view within your URLconf without having to update the setting.

---

**Note:** The `login_required` decorator does NOT check the `is_active` flag on a user, but the default `AUTHENTICATION_BACKENDS` reject inactive users.

---

#### See also:

If you are writing custom views for Django's admin (or need the same authorization check that the built-in views use), you may find the `django.contrib.admin.views.decorators.staff_member_required()` decorator a useful alternative to `login_required()`.

### The LoginRequired mixin

When using *class-based views*, you can achieve the same behavior as with `login_required` by using the `LoginRequiredMixin`. This mixin should be at the leftmost position in the inheritance list.

#### class LoginRequiredMixin

If a view is using this mixin, all requests by non-authenticated users will be redirected to the login page or shown an HTTP 403 Forbidden error, depending on the `raise_exception` parameter.

You can set any of the parameters of *AccessMixin* to customize the handling of unauthorized users:

```
from django.contrib.auth.mixins import LoginRequiredMixin

class MyView(LoginRequiredMixin, View):
    login_url = '/login/'
    redirect_field_name = 'redirect_to'
```

---

**Note:** Just as the `login_required` decorator, this mixin does NOT check the `is_active` flag on a user, but the default `AUTHENTICATION_BACKENDS` reject inactive users.

---

### Limiting access to logged-in users that pass a test

To limit access based on certain permissions or some other test, you'd do essentially the same thing as described in the previous section.

The simple way is to run your test on `request.user` in the view directly. For example, this view checks to make sure the user has an email in the desired domain and if not, redirects to the login page:

```
from django.shortcuts import redirect

def my_view(request):
    if not request.user.email.endswith('@example.com'):
        return redirect('/login/?next=%s' % request.path)
    # ...
```

**user\_passes\_test** (*test\_func*, *login\_url=None*, *redirect\_field\_name='next'*)

As a shortcut, you can use the convenient `user_passes_test` decorator which performs a redirect when the callable returns `False`:

```
from django.contrib.auth.decorators import user_passes_test

def email_check(user):
    return user.email.endswith('@example.com')

@user_passes_test(email_check)
def my_view(request):
    ...
```

`user_passes_test()` takes a required argument: a callable that takes a `User` object and returns `True` if the user is allowed to view the page. Note that `user_passes_test()` does not automatically check that the `User` is not anonymous.

`user_passes_test()` takes two optional arguments:

**login\_url** Lets you specify the URL that users who don't pass the test will be redirected to. It may be a login page and defaults to `settings.LOGIN_URL` if you don't specify one.

**redirect\_field\_name** Same as for `login_required()`. Setting it to `None` removes it from the URL, which you may want to do if you are redirecting users that don't pass the test to a non-login page where there's no "next page".

For example:

```
@user_passes_test(email_check, login_url='/login/')
def my_view(request):
    ...
```

### class `UserPassesTestMixin`

When using *class-based views*, you can use the `UserPassesTestMixin` to do this.

#### `test_func()`

You have to override the `test_func()` method of the class to provide the test that is performed. Furthermore, you can set any of the parameters of `AccessMixin` to customize the handling of unauthorized users:

```
from django.contrib.auth.mixins import UserPassesTestMixin

class MyView(UserPassesTestMixin, View):

    def test_func(self):
        return self.request.user.email.endswith('@example.com')
```

#### `get_test_func()`

You can also override the `get_test_func()` method to have the mixin use a differently named function for its checks (instead of `test_func()`).

### Stacking `UserPassesTestMixin`

Due to the way `UserPassesTestMixin` is implemented, you cannot stack them in your inheritance list. The following does NOT work:

```
class TestMixin1(UserPassesTestMixin):
    def test_func(self):
        return self.request.user.email.endswith('@example.com')

class TestMixin2(UserPassesTestMixin):
    def test_func(self):
        return self.request.user.username.startswith('django')

class MyView(TestMixin1, TestMixin2, View):
    ...
```

If `TestMixin1` would call `super()` and take that result into account, `TestMixin1` wouldn't work standalone anymore.

## The `permission_required` decorator

### `permission_required` (*perm*, *login\_url=None*, *raise\_exception=False*)

It's a relatively common task to check whether a user has a particular permission. For that reason, Django provides a shortcut for that case: the `permission_required()` decorator:

```
from django.contrib.auth.decorators import permission_required

@permission_required('polls.can_vote')
def my_view(request):
    ...
```

Just like the `has_perm()` method, permission names take the form "`<app label>.<permission codename>`" (i.e. `polls.can_vote` for a permission on a model in the `polls` application).

The decorator may also take an iterable of permissions, in which case the user must have all of the permissions in order to access the view.

Note that `permission_required()` also takes an optional `login_url` parameter:

```
from django.contrib.auth.decorators import permission_required

@permission_required('polls.can_vote', login_url='/loginpage/')
def my_view(request):
    ...
```

As in the `login_required()` decorator, `login_url` defaults to `settings.LOGIN_URL`.

If the `raise_exception` parameter is given, the decorator will raise `PermissionDenied`, prompting the *403 (HTTP Forbidden) view* instead of redirecting to the login page.

If you want to use `raise_exception` but also give your users a chance to login first, you can add the `login_required()` decorator:

```
from django.contrib.auth.decorators import login_required, permission_required

@login_required
@permission_required('polls.can_vote', raise_exception=True)
def my_view(request):
    ...
```

In older versions, the `permission` parameter only worked with strings, lists, and tuples instead of strings and any iterable.

## The `PermissionRequiredMixin` mixin

To apply permission checks to *class-based views*, you can use the `PermissionRequiredMixin`:

### class `PermissionRequiredMixin`

This mixin, just like the `permission_required` decorator, checks whether the user accessing a view has all given permissions. You should specify the permission (or an iterable of permissions) using the `permission_required` parameter:

```
from django.contrib.auth.mixins import PermissionRequiredMixin

class MyView(PermissionRequiredMixin, View):
    permission_required = 'polls.can_vote'
    # Or multiple of permissions:
    permission_required = ('polls.can_open', 'polls.can_edit')
```

You can set any of the parameters of `AccessMixin` to customize the handling of unauthorized users.

You may also override these methods:

#### `get_permission_required()`

Returns an iterable of permission names used by the mixin. Defaults to the `permission_required` attribute, converted to a tuple if necessary.

#### `has_permission()`

Returns a boolean denoting whether the current user has permission to execute the decorated view.

By default, this returns the result of calling `has_perms()` with the list of permissions returned by `get_permission_required()`.

## Redirecting unauthorized requests in class-based views

To ease the handling of access restrictions in *class-based views*, the `AccessMixin` can be used to redirect a user to the login page or issue an HTTP 403 Forbidden response.

class `AccessMixin`

### `login_url`

Default return value for `get_login_url()`. Defaults to `None` in which case `get_login_url()` falls back to `settings.LOGIN_URL`.

### `permission_denied_message`

Default return value for `get_permission_denied_message()`. Defaults to an empty string.

### `redirect_field_name`

Default return value for `get_redirect_field_name()`. Defaults to `"next"`.

### `raise_exception`

If this attribute is set to `True`, a `PermissionDenied` exception will be raised instead of the redirect. Defaults to `False`.

### `get_login_url()`

Returns the URL that users who don't pass the test will be redirected to. Returns `login_url` if set, or `settings.LOGIN_URL` otherwise.

### `get_permission_denied_message()`

When `raise_exception` is `True`, this method can be used to control the error message passed to the error handler for display to the user. Returns the `permission_denied_message` attribute by default.

### `get_redirect_field_name()`

Returns the name of the query parameter that will contain the URL the user should be redirected to after a successful login. If you set this to `None`, a query parameter won't be added. Returns the `redirect_field_name` attribute by default.

### `handle_no_permission()`

Depending on the value of `raise_exception`, the method either raises a `PermissionDenied` exception or redirects the user to the `login_url`, optionally including the `redirect_field_name` if it is set.

## Session invalidation on password change

Session verification is enabled and mandatory in Django 1.10 (there's no way to disable it) regardless of whether or not `SessionAuthenticationMiddleware` is enabled. In older versions, this protection only applies if `django.contrib.auth.middleware.SessionAuthenticationMiddleware` is enabled in `MIDDLEWARE`.

If your `AUTH_USER_MODEL` inherits from `AbstractBaseUser` or implements its own `get_session_auth_hash()` method, authenticated sessions will include the hash returned by this function. In the `AbstractBaseUser` case, this is an HMAC of the password field. Django verifies that the hash in the session for each request matches the one that's computed during the request. This allows a user to log out all of their sessions by changing their password.

The default password change views included with Django, `password_change()` and the `user_change_password` view in the `django.contrib.auth` admin, update the session with the new

password hash so that a user changing their own password won't log themselves out. If you have a custom password change view and wish to have similar behavior, use the `update_session_auth_hash()` function. In this case, however, if a user also wants to invalidate the session from which they're changing their password (for example, if they believe the session cookie on their machine was stolen), then they also need to log out that session.

`update_session_auth_hash(request, user)`

This function takes the current request and the updated user object from which the new session hash will be derived and updates the session hash appropriately. Example usage:

```
from django.contrib.auth import update_session_auth_hash

def password_change(request):
    if request.method == 'POST':
        form = PasswordChangeForm(user=request.user, data=request.POST)
        if form.is_valid():
            form.save()
            update_session_auth_hash(request, form.user)
    else:
        ...
```

---

**Note:** Since `get_session_auth_hash()` is based on `SECRET_KEY`, updating your site to use a new secret will invalidate all existing sessions.

---

## Authentication Views

Django provides several views that you can use for handling login, logout, and password management. These make use of the *stock auth forms* but you can pass in your own forms as well.

Django provides no default template for the authentication views. You should create your own templates for the views you want to use. The template context is documented in each view, see *All authentication views*.

## Using the views

There are different methods to implement these views in your project. The easiest way is to include the provided URLconf in `django.contrib.auth.urls` in your own URLconf, for example:

```
urlpatterns = [
    url('^', include('django.contrib.auth.urls')),
]
```

This will include the following URL patterns:

```
^login/$ [name='login']
^logout/$ [name='logout']
^password_change/$ [name='password_change']
^password_change/done/$ [name='password_change_done']
^password_reset/$ [name='password_reset']
^password_reset/done/$ [name='password_reset_done']
^reset/(?P<uidb64>[0-9A-Za-z_-]+)/(?P<token>[0-9A-Za-z]{1,13}-[0-9A-Za-z]{1,20})/$_
↪ [name='password_reset_confirm']
^reset/done/$ [name='password_reset_complete']
```

The views provide a URL name for easier reference. See *the URL documentation* for details on using named URL patterns.

If you want more control over your URLs, you can reference a specific view in your URLconf:

```
from django.contrib.auth import views as auth_views

urlpatterns = [
    url('^change-password/$', auth_views.password_change),
]
```

The views have optional arguments you can use to alter the behavior of the view. For example, if you want to change the template name a view uses, you can provide the `template_name` argument. A way to do this is to provide keyword arguments in the URLconf, these will be passed on to the view. For example:

```
urlpatterns = [
    url(
        '^change-password/$',
        auth_views.password_change,
        {'template_name': 'change-password.html'}
    ),
]
```

All views return a *TemplateResponse* instance, which allows you to easily customize the response data before rendering. A way to do this is to wrap a view in your own view:

```
from django.contrib.auth import views

def change_password(request):
    template_response = views.password_change(request)
    # Do something with `template_response`
    return template_response
```

For more details, see the [TemplateResponse documentation](#).

## All authentication views

This is a list with all the views `django.contrib.auth` provides. For implementation details see [Using the views](#).

**login** (*request*, *template\_name*='registration/login.html', *redirect\_field\_name*='next', *authentication\_form*=*AuthenticationForm*, *current\_app*=*None*, *extra\_context*=*None*, *redirect\_authenticated\_user*=*False*)

**URL name:** login

See [the URL documentation](#) for details on using named URL patterns.

### Optional arguments:

- `template_name`: The name of a template to display for the view used to log the user in. Defaults to `registration/login.html`.
- `redirect_field_name`: The name of a GET field containing the URL to redirect to after login. Defaults to `next`.
- `authentication_form`: A callable (typically just a form class) to use for authentication. Defaults to `AuthenticationForm`.
- `current_app`: A hint indicating which application contains the current view. See the [namespaced URL resolution strategy](#) for more information.

- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.
- `redirect_authenticated_user`: A boolean that controls whether or not authenticated users accessing the login page will be redirected as if they had just successfully logged in. Defaults to `False`.

**Warning:** If you enable `redirect_authenticated_user`, other websites will be able to determine if their visitors are authenticated on your site by requesting redirect URLs to image files on your website. To avoid this “social media fingerprinting” information leakage, host all images and your favicon on a separate domain.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

The `redirect_authenticated_user` parameter was added.

Here’s what `django.contrib.auth.views.login` does:

- If called via `GET`, it displays a login form that `POSTs` to the same URL. More on this in a bit.
- If called via `POST` with user submitted credentials, it tries to log the user in. If login is successful, the view redirects to the URL specified in `next`. If `next` isn’t provided, it redirects to `settings.LOGIN_REDIRECT_URL` (which defaults to `/accounts/profile/`). If login isn’t successful, it redisplay the login form.

It’s your responsibility to provide the html for the login template, called `registration/login.html` by default. This template gets passed four template context variables:

- `form`: A `Form` object representing the `AuthenticationForm`.
- `next`: The URL to redirect to after successful login. This may contain a query string, too.
- `site`: The current `Site`, according to the `SITE_ID` setting. If you don’t have the site framework installed, this will be set to an instance of `RequestSite`, which derives the site name and domain from the current `HttpRequest`.
- `site_name`: An alias for `site.name`. If you don’t have the site framework installed, this will be set to the value of `request.META['SERVER_NAME']`. For more on sites, see *The “sites” framework*.

If you’d prefer not to call the template `registration/login.html`, you can pass the `template_name` parameter via the extra arguments to the view in your URLconf. For example, this URLconf line would use `myapp/login.html` instead:

```
url(r'^accounts/login/$', auth_views.login, {'template_name': 'myapp/login.html'})
↪),
```

You can also specify the name of the `GET` field which contains the URL to redirect to after login by passing `redirect_field_name` to the view. By default, the field is called `next`.

Here’s a sample `registration/login.html` template you can use as a starting point. It assumes you have a `base.html` template that defines a content block:

```
{% extends "base.html" %}

{% block content %}

{% if form.errors %}
<p>Your username and password didn't match. Please try again.</p>
{% endif %}
```

```

{% if next %}
    {% if user.is_authenticated %}
        <p>Your account doesn't have access to this page. To proceed,
        please login with an account that has access.</p>
    {% else %}
        <p>Please login to see this page.</p>
    {% endif %}
{% endif %}

<form method="post" action="{% url 'login' %}">
{% csrf_token %}
<table>
<tr>
    <td>{{ form.username.label_tag }}</td>
    <td>{{ form.username }}</td>
</tr>
<tr>
    <td>{{ form.password.label_tag }}</td>
    <td>{{ form.password }}</td>
</tr>
</table>

<input type="submit" value="login" />
<input type="hidden" name="next" value="{{ next }}" />
</form>

{# Assumes you setup the password_reset view in your URLconf #}
<p><a href="{% url 'password_reset' %}">Lost password?</a></p>

{% endblock %}

```

If you have customized authentication (see *Customizing Authentication*) you can pass a custom authentication form to the login view via the `authentication_form` parameter. This form must accept a `request` keyword argument in its `__init__` method, and provide a `get_user()` method which returns the authenticated user object (this method is only ever called after successful form validation).

**logout** (*request*, *next\_page=None*, *template\_name='registration/logged\_out.html'*, *redirect\_field\_name='next'*, *current\_app=None*, *extra\_context=None*)  
Logs a user out.

**URL name:** `logout`

**Optional arguments:**

- `next_page`: The URL to redirect to after logout. Defaults to `settings.LOGOUT_REDIRECT_URL` if not supplied.
- `template_name`: The full name of a template to display after logging the user out. Defaults to `registration/logged_out.html` if no argument is supplied.
- `redirect_field_name`: The name of a GET field containing the URL to redirect to after log out. Defaults to `next`. Overrides the `next_page` URL if the given GET parameter is passed.
- `current_app`: A hint indicating which application contains the current view. See the *namespaced URL resolution strategy* for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

**Template context:**

- `title`: The string “Logged out”, localized.
- `site`: The current *Site*, according to the `SITE_ID` setting. If you don’t have the site framework installed, this will be set to an instance of *RequestSite*, which derives the site name and domain from the current *HttpRequest*.
- `site_name`: An alias for `site.name`. If you don’t have the site framework installed, this will be set to the value of `request.META['SERVER_NAME']`. For more on sites, see *The “sites” framework*.

**logout\_then\_login** (*request*, *login\_url=None*, *current\_app=None*, *extra\_context=None*)

Logs a user out, then redirects to the login page.

**URL name:** No default URL provided

**Optional arguments:**

- `login_url`: The URL of the login page to redirect to. Defaults to `settings.LOGIN_URL` if not supplied.
- `current_app`: A hint indicating which application contains the current view. See the *namespaced URL resolution strategy* for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

**password\_change** (*request*, *template\_name='registration/password\_change\_form.html'*,  
*post\_change\_redirect=None*, *password\_change\_form=PasswordChangeForm*, *current\_app=None*, *extra\_context=None*)

Allows a user to change their password.

**URL name:** `password_change`

**Optional arguments:**

- `template_name`: The full name of a template to use for displaying the password change form. Defaults to `registration/password_change_form.html` if not supplied.
- `post_change_redirect`: The URL to redirect to after a successful password change.
- `password_change_form`: A custom “change password” form which must accept a `user` keyword argument. The form is responsible for actually changing the user’s password. Defaults to *PasswordChangeForm*.
- `current_app`: A hint indicating which application contains the current view. See the *namespaced URL resolution strategy* for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

**Template context:**

- `form`: The password change form (see `password_change_form` above).

**password\_change\_done** (*request*, *template\_name='registration/password\_change\_done.html'*, *current\_app=None*, *extra\_context=None*)

The page shown after a user has changed their password.

**URL name:** `password_change_done`

**Optional arguments:**

- `template_name`: The full name of a template to use. Defaults to `registration/password_change_done.html` if not supplied.
- `current_app`: A hint indicating which application contains the current view. See the [namespaced URL resolution strategy](#) for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

```
password_reset (request, template_name='registration/password_reset_form.html',
                 email_template_name='registration/password_reset_email.html', sub-
                 ject_template_name='registration/password_reset_subject.txt', pass-
                 word_reset_form=PasswordResetForm, token_generator=default_token_generator,
                 post_reset_redirect=None, from_email=None, current_app=None, extra_context=None,
                 html_email_template_name=None, extra_email_context=None)
```

Allows a user to reset their password by generating a one-time use link that can be used to reset the password, and sending that link to the user's registered email address.

If the email address provided does not exist in the system, this view won't send an email, but the user won't receive any error message either. This prevents information leaking to potential attackers. If you want to provide an error message in this case, you can subclass `PasswordResetForm` and use the `password_reset_form` argument.

Users flagged with an unusable password (see `set_unusable_password()`) aren't allowed to request a password reset to prevent misuse when using an external authentication source like LDAP. Note that they won't receive any error message since this would expose their account's existence but no mail will be sent either.

**URL name:** `password_reset`

**Optional arguments:**

- `template_name`: The full name of a template to use for displaying the password reset form. Defaults to `registration/password_reset_form.html` if not supplied.
- `email_template_name`: The full name of a template to use for generating the email with the reset password link. Defaults to `registration/password_reset_email.html` if not supplied.
- `subject_template_name`: The full name of a template to use for the subject of the email with the reset password link. Defaults to `registration/password_reset_subject.txt` if not supplied.
- `password_reset_form`: Form that will be used to get the email of the user to reset the password for. Defaults to `PasswordResetForm`.
- `token_generator`: Instance of the class to check the one time link. This will default to `default_token_generator`, it's an instance of `django.contrib.auth.tokens.PasswordResetTokenGenerator`.
- `post_reset_redirect`: The URL to redirect to after a successful password reset request.
- `from_email`: A valid email address. By default Django uses the `DEFAULT_FROM_EMAIL`.
- `current_app`: A hint indicating which application contains the current view. See the [namespaced URL resolution strategy](#) for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.
- `html_email_template_name`: The full name of a template to use for generating a text/html multipart email with the password reset link. By default, HTML email is not sent.

- `extra_email_context`: A dictionary of context data that will be available in the email template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

The `extra_email_context` parameter was added.

#### Template context:

- `form`: The form (see `password_reset_form` above) for resetting the user’s password.

#### Email template context:

- `email`: An alias for `user.email`
- `user`: The current *User*, according to the email form field. Only active users are able to reset their passwords (`User.is_active` is `True`).
- `site_name`: An alias for `site.name`. If you don’t have the site framework installed, this will be set to the value of `request.META[ 'SERVER_NAME' ]`. For more on sites, see *The “sites” framework*.
- `domain`: An alias for `site.domain`. If you don’t have the site framework installed, this will be set to the value of `request.get_host()`.
- `protocol`: `http` or `https`
- `uid`: The user’s primary key encoded in base 64.
- `token`: Token to check that the reset link is valid.

Sample `registration/password_reset_email.html` (email body template):

```
Someone asked for password reset for email {{ email }}. Follow the link below:
{{ protocol }}://{{ domain }}{% url 'password_reset_confirm' uidb64=uid_
↪token=token %}
```

The same template context is used for subject template. Subject must be single line plain text string.

`password_reset_done` (*request*, *template\_name*='registration/password\_reset\_done.html', *current\_app*=None, *extra\_context*=None)

The page shown after a user has been emailed a link to reset their password. This view is called by default if the `password_reset()` view doesn’t have an explicit `post_reset_redirect` URL set.

**URL name:** `password_reset_done`

---

**Note:** If the email address provided does not exist in the system, the user is inactive, or has an unusable password, the user will still be redirected to this view but no email will be sent.

---

#### Optional arguments:

- `template_name`: The full name of a template to use. Defaults to `registration/password_reset_done.html` if not supplied.
- `current_app`: A hint indicating which application contains the current view. See the *namespaced URL resolution strategy* for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

**password\_reset\_confirm** (*request*, *uidb64=None*, *token=None*, *template\_name='registration/password\_reset\_confirm.html'*, *token\_generator=default\_token\_generator*, *set\_password\_form=SetPasswordForm*, *post\_reset\_redirect=None*, *current\_app=None*, *extra\_context=None*)

Presents a form for entering a new password.

**URL name:** `password_reset_confirm`

**Optional arguments:**

- `uidb64`: The user's id encoded in base 64. Defaults to `None`.
- `token`: Token to check that the password is valid. Defaults to `None`.
- `template_name`: The full name of a template to display the confirm password view. Default value is `registration/password_reset_confirm.html`.
- `token_generator`: Instance of the class to check the password. This will default to `default_token_generator`, it's an instance of `django.contrib.auth.tokens.PasswordResetTokenGenerator`.
- `set_password_form`: Form that will be used to set the password. Defaults to `SetPasswordForm`
- `post_reset_redirect`: URL to redirect after the password reset done. Defaults to `None`.
- `current_app`: A hint indicating which application contains the current view. See the [namespaced URL resolution strategy](#) for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

**Template context:**

- `form`: The form (see `set_password_form` above) for setting the new user's password.
- `validlink`: Boolean, True if the link (combination of `uidb64` and `token`) is valid or unused yet.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

**password\_reset\_complete** (*request*, *template\_name='registration/password\_reset\_complete.html'*, *current\_app=None*, *extra\_context=None*)

Presents a view which informs the user that the password has been successfully changed.

**URL name:** `password_reset_complete`

**Optional arguments:**

- `template_name`: The full name of a template to display the view. Defaults to `registration/password_reset_complete.html`.
- `current_app`: A hint indicating which application contains the current view. See the [namespaced URL resolution strategy](#) for more information.
- `extra_context`: A dictionary of context data that will be added to the default context data passed to the template.

Deprecated since version 1.9: The `current_app` parameter is deprecated and will be removed in Django 2.0. Callers should set `request.current_app` instead.

## Helper functions

**redirect\_to\_login** (*next*, *login\_url=None*, *redirect\_field\_name='next'*)

Redirects to the login page, and then back to another URL after a successful login.

**Required arguments:**

- `next`: The URL to redirect to after a successful login.

**Optional arguments:**

- `login_url`: The URL of the login page to redirect to. Defaults to `settings.LOGIN_URL` if not supplied.
- `redirect_field_name`: The name of a GET field containing the URL to redirect to after log out. Overrides `next` if the given GET parameter is passed.

**Built-in forms**

If you don't want to use the built-in views, but want the convenience of not having to write forms for this functionality, the authentication system provides several built-in forms located in `django.contrib.auth.forms`:

---

**Note:** The built-in authentication forms make certain assumptions about the user model that they are working with. If you're using a *custom user model*, it may be necessary to define your own forms for the authentication system. For more information, refer to the documentation about *using the built-in authentication forms with custom user models*.

---

**class AdminPasswordChangeForm**

A form used in the admin interface to change a user's password.

Takes the `user` as the first positional argument.

**class AuthenticationForm**

A form for logging a user in.

Takes `request` as its first positional argument, which is stored on the form instance for use by sub-classes.

**confirm\_login\_allowed** (*user*)

By default, `AuthenticationForm` rejects users whose `is_active` flag is set to `False`. You may override this behavior with a custom policy to determine which users can log in. Do this with a custom form that subclasses `AuthenticationForm` and overrides the `confirm_login_allowed()` method. This method should raise a `ValidationError` if the given user may not log in.

For example, to allow all users to log in regardless of "active" status:

```
from django.contrib.auth.forms import AuthenticationForm

class AuthenticationFormWithInactiveUsersOkay(AuthenticationForm):
    def confirm_login_allowed(self, user):
        pass
```

(In this case, you'll also need to use an authentication backend that allows inactive users, such as as `AllowAllUsersModelBackend`.)

Or to allow only some active users to log in:

```
class PickyAuthenticationForm(AuthenticationForm):
    def confirm_login_allowed(self, user):
        if not user.is_active:
            raise forms.ValidationError(
                _("This account is inactive."),
                code='inactive',
            )
        if user.username.startswith('b'):
```

```
raise forms.ValidationError(
    _("Sorry, accounts starting with 'b' aren't welcome here."),
    code='no_b_users',
)
```

**class PasswordChangeForm**

A form for allowing a user to change their password.

**class PasswordResetForm**

A form for generating and emailing a one-time use link to reset a user's password.

**send\_mail** (*subject\_template\_name*, *email\_template\_name*, *context*, *from\_email*, *to\_email*, *html\_email\_template\_name=None*)

Uses the arguments to send an `EmailMultiAlternatives`. Can be overridden to customize how the email is sent to the user.

**Parameters**

- **subject\_template\_name** – the template for the subject.
- **email\_template\_name** – the template for the email body.
- **context** – context passed to the `subject_template`, `email_template`, and `html_email_template` (if it is not `None`).
- **from\_email** – the sender's email.
- **to\_email** – the email of the requester.
- **html\_email\_template\_name** – the template for the HTML body; defaults to `None`, in which case a plain text email is sent.

By default, `save()` populates the `context` with the same variables that `password_reset()` passes to its email context.

**class SetPasswordForm**

A form that lets a user change their password without entering the old password.

**class UserChangeForm**

A form used in the admin interface to change a user's information and permissions.

**class UserCreationForm**

A `ModelForm` for creating a new user.

It has three fields: `username` (from the user model), `password1`, and `password2`. It verifies that `password1` and `password2` match, validates the password using `validate_password()`, and sets the user's password using `set_password()`.

## Authentication data in templates

The currently logged-in user and their permissions are made available in the `template context` when you use `RequestContext`.

---

**Technicality**

Technically, these variables are only made available in the template context if you use `RequestContext` and the `'django.contrib.auth.context_processors.auth'` context processor is enabled. It is in the default generated settings file. For more, see the `RequestContext docs`.

---

## Users

When rendering a template *RequestContext*, the currently logged-in user, either a *User* instance or an *AnonymousUser* instance, is stored in the template variable `{{ user }}`:

```
{% if user.is_authenticated %}
    <p>Welcome, {{ user.username }}. Thanks for logging in.</p>
{% else %}
    <p>Welcome, new user. Please log in.</p>
{% endif %}
```

This template context variable is not available if a *RequestContext* is not being used.

## Permissions

The currently logged-in user's permissions are stored in the template variable `{{ perms }}`. This is an instance of `django.contrib.auth.context_processors.PermWrapper`, which is a template-friendly proxy of permissions.

In the `{{ perms }}` object, single-attribute lookup is a proxy to *User.has\_module\_perms*. This example would display `True` if the logged-in user had any permissions in the `foo` app:

```
{{ perms.foo }}
```

Two-level-attribute lookup is a proxy to *User.has\_perm*. This example would display `True` if the logged-in user had the permission `foo.can_vote`:

```
{{ perms.foo.can_vote }}
```

Thus, you can check permissions in template `{% if %}` statements:

```
{% if perms.foo %}
    <p>You have permission to do something in the foo app.</p>
    {% if perms.foo.can_vote %}
        <p>You can vote!</p>
    {% endif %}
    {% if perms.foo.can_drive %}
        <p>You can drive!</p>
    {% endif %}
{% else %}
    <p>You don't have permission to do anything in the foo app.</p>
{% endif %}
```

It is possible to also look permissions up by `{% if in %}` statements. For example:

```
{% if 'foo' in perms %}
    {% if 'foo.can_vote' in perms %}
        <p>In lookup works, too.</p>
    {% endif %}
{% endif %}
```

## Managing users in the admin

When you have both `django.contrib.admin` and `django.contrib.auth` installed, the admin provides a convenient way to view and manage users, groups, and permissions. Users can be created and deleted like any Django

model. Groups can be created, and permissions can be assigned to users or groups. A log of user edits to models made within the admin is also stored and displayed.

## Creating users

You should see a link to “Users” in the “Auth” section of the main admin index page. The “Add user” admin page is different than standard admin pages in that it requires you to choose a username and password before allowing you to edit the rest of the user’s fields.

Also note: if you want a user account to be able to create users using the Django admin site, you’ll need to give them permission to add users *and* change users (i.e., the “Add user” and “Change user” permissions). If an account has permission to add users but not to change them, that account won’t be able to add users. Why? Because if you have permission to add users, you have the power to create superusers, which can then, in turn, change other users. So Django requires add *and* change permissions as a slight security measure.

Be thoughtful about how you allow users to manage permissions. If you give a non-superuser the ability to edit users, this is ultimately the same as giving them superuser status because they will be able to elevate permissions of users including themselves!

## Changing passwords

User passwords are not displayed in the admin (nor stored in the database), but the *password storage details* are displayed. Included in the display of this information is a link to a password change form that allows admins to change user passwords.

### 3.10.2 Password management in Django

Password management is something that should generally not be reinvented unnecessarily, and Django endeavors to provide a secure and flexible set of tools for managing user passwords. This document describes how Django stores passwords, how the storage hashing can be configured, and some utilities to work with hashed passwords.

#### See also:

Even though users may use strong passwords, attackers might be able to eavesdrop on their connections. Use *HTTPS* to avoid sending passwords (or any other sensitive data) over plain HTTP connections because they will be vulnerable to password sniffing.

## How Django stores passwords

Django provides a flexible password storage system and uses PBKDF2 by default.

The *password* attribute of a *User* object is a string in this format:

```
<algorithm>${iterations}>${salt}>${hash}>
```

Those are the components used for storing a User’s password, separated by the dollar-sign character and consist of: the hashing algorithm, the number of algorithm iterations (work factor), the random salt, and the resulting password hash. The algorithm is one of a number of one-way hashing or password storage algorithms Django can use; see below. Iterations describe the number of times the algorithm is run over the hash. Salt is the random seed used and the hash is the result of the one-way function.

By default, Django uses the **PBKDF2** algorithm with a SHA256 hash, a password stretching mechanism recommended by **NIST**. This should be sufficient for most users: it’s quite secure, requiring massive amounts of computing time to break.

However, depending on your requirements, you may choose a different algorithm, or even use a custom algorithm to match your specific security situation. Again, most users shouldn't need to do this – if you're not sure, you probably don't. If you do, please read on:

Django chooses the algorithm to use by consulting the `PASSWORD_HASHERS` setting. This is a list of hashing algorithm classes that this Django installation supports. The first entry in this list (that is, `settings.PASSWORD_HASHERS[0]`) will be used to store passwords, and all the other entries are valid hashers that can be used to check existing passwords. This means that if you want to use a different algorithm, you'll need to modify `PASSWORD_HASHERS` to list your preferred algorithm first in the list.

The default for `PASSWORD_HASHERS` is:

```
PASSWORD_HASHERS = [
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2SHA1PasswordHasher',
    'django.contrib.auth.hashers.Argon2PasswordHasher',
    'django.contrib.auth.hashers.BCryptSHA256PasswordHasher',
    'django.contrib.auth.hashers.BCryptPasswordHasher',
]
```

This means that Django will use `PBKDF2` to store all passwords but will support checking passwords stored with `PBKDF2SHA1`, `argon2`, and `bcrypt`.

The next few sections describe a couple of common ways advanced users may want to modify this setting.

## Using Argon2 with Django

`Argon2` is the winner of the 2015 [Password Hashing Competition](#), a community organized open competition to select a next generation hashing algorithm. It's designed not to be easier to compute on custom hardware than it is to compute on an ordinary CPU.

`Argon2` is not the default for Django because it requires a third-party library. The Password Hashing Competition panel, however, recommends immediate use of `Argon2` rather than the other algorithms supported by Django.

To use `Argon2` as your default storage algorithm, do the following:

1. Install the `argon2-ffi` library. This can be done by running `pip install django[argon2]`, which is equivalent to `pip install argon2-ffi` (along with any version requirement from Django's `setup.py`).
2. Modify `PASSWORD_HASHERS` to list `Argon2PasswordHasher` first. That is, in your settings file, you'd put:

```
PASSWORD_HASHERS = [
    'django.contrib.auth.hashers.Argon2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2SHA1PasswordHasher',
    'django.contrib.auth.hashers.BCryptSHA256PasswordHasher',
    'django.contrib.auth.hashers.BCryptPasswordHasher',
]
```

Keep and/or add any entries in this list if you need Django to *upgrade passwords*.

## Using bcrypt with Django

`Bcrypt` is a popular password storage algorithm that's specifically designed for long-term password storage. It's not the default used by Django since it requires the use of third-party libraries, but since many people may want to use it

Django supports bcrypt with minimal effort.

To use Bcrypt as your default storage algorithm, do the following:

1. Install the `bcrypt` library. This can be done by running `pip install django[bcrypt]`, which is equivalent to `pip install bcrypt` (along with any version requirement from Django's `setup.py`).
2. Modify `PASSWORD_HASHERS` to list `BCryptSHA256PasswordHasher` first. That is, in your settings file, you'd put:

```
PASSWORD_HASHERS = [  
    'django.contrib.auth.hashers.BCryptSHA256PasswordHasher',  
    'django.contrib.auth.hashers.BCryptPasswordHasher',  
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',  
    'django.contrib.auth.hashers.PBKDF2SHA1PasswordHasher',  
    'django.contrib.auth.hashers.Argon2PasswordHasher',  
]
```

Keep and/or add any entries in this list if you need Django to *upgrade passwords*.

That's it – now your Django install will use Bcrypt as the default storage algorithm.

---

### Password truncation with `BCryptPasswordHasher`

The designers of `bcrypt` truncate all passwords at 72 characters which means that `bcrypt(password_with_100_chars) == bcrypt(password_with_100_chars[:72])`. The original `BCryptPasswordHasher` does not have any special handling and thus is also subject to this hidden password length limit. `BCryptSHA256PasswordHasher` fixes this by first hashing the password using `sha256`. This prevents the password truncation and so should be preferred over the `BCryptPasswordHasher`. The practical ramification of this truncation is pretty marginal as the average user does not have a password greater than 72 characters in length and even being truncated at 72 the compute power required to brute force `bcrypt` in any useful amount of time is still astronomical. Nonetheless, we recommend you use `BCryptSHA256PasswordHasher` anyway on the principle of “better safe than sorry”.

---

### Other `bcrypt` implementations

There are several other implementations that allow `bcrypt` to be used with Django. Django's `bcrypt` support is NOT directly compatible with these. To upgrade, you will need to modify the hashes in your database to be in the form `bcrypt$(raw bcrypt output)`. For example: `bcrypt$$2a$12$NT0I31Sa7ihGEWpka9ASYrEFkhuTNeBQ2xfZskIiiJeyFXhRgS.Sy`.

---

## Increasing the work factor

### PBKDF2 and `bcrypt`

The PBKDF2 and `bcrypt` algorithms use a number of iterations or rounds of hashing. This deliberately slows down attackers, making attacks against hashed passwords harder. However, as computing power increases, the number of iterations needs to be increased. We've chosen a reasonable default (and will increase it with each release of Django), but you may wish to tune it up or down, depending on your security needs and available processing power. To do so, you'll subclass the appropriate algorithm and override the `iterations` parameters. For example, to increase the number of iterations used by the default PBKDF2 algorithm:

1. Create a subclass of `django.contrib.auth.hashers.PBKDF2PasswordHasher`:

```
from django.contrib.auth.hashers import PBKDF2PasswordHasher

class MyPBKDF2PasswordHasher(PBKDF2PasswordHasher):
    """
    A subclass of PBKDF2PasswordHasher that uses 100 times more iterations.
    """
    iterations = PBKDF2PasswordHasher.iterations * 100
```

Save this somewhere in your project. For example, you might put this in a file like `myproject/hashers.py`.

2. Add your new hasher as the first entry in `PASSWORD_HASHERS`:

```
PASSWORD_HASHERS = [
    'myproject.hashers.MyPBKDF2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2SHA1PasswordHasher',
    'django.contrib.auth.hashers.Argon2PasswordHasher',
    'django.contrib.auth.hashers.BCryptSHA256PasswordHasher',
    'django.contrib.auth.hashers.BCryptPasswordHasher',
]
```

That's it – now your Django install will use more iterations when it stores passwords using PBKDF2.

## Argon2

Argon2 has three attributes that can be customized:

1. `time_cost` controls the number of iterations within the hash.
2. `memory_cost` controls the size of memory that must be used during the computation of the hash.
3. `parallelism` controls how many CPUs the computation of the hash can be parallelized on.

The default values of these attributes are probably fine for you. If you determine that the password hash is too fast or too slow, you can tweak it as follows:

1. Choose `parallelism` to be the number of threads you can spare computing the hash.
2. Choose `memory_cost` to be the KiB of memory you can spare.
3. Adjust `time_cost` and measure the time hashing a password takes. Pick a `time_cost` that takes an acceptable time for you. If `time_cost` set to 1 is unacceptably slow, lower `memory_cost`.

---

### memory\_cost interpretation

The `argon2` command-line utility and some other libraries interpret the `memory_cost` parameter differently from the value that Django uses. The conversion is given by `memory_cost == 2 ** memory_cost_commandline`.

---

## Password upgrading

When users log in, if their passwords are stored with anything other than the preferred algorithm, Django will automatically upgrade the algorithm to the preferred one. This means that old installs of Django will get automatically more secure as users log in, and it also means that you can switch to new (and better) storage algorithms as they get invented.

However, Django can only upgrade passwords that use algorithms mentioned in `PASSWORD_HASHERS`, so as you upgrade to new systems you should make sure never to *remove* entries from this list. If you do, users using unmentioned algorithms won't be able to upgrade. Hashed passwords will be updated when increasing (or decreasing) the number of PBKDF2 iterations or bcrypt rounds.

Be aware that if all the passwords in your database aren't encoded in the default hasher's algorithm, you may be vulnerable to a user enumeration timing attack due to a difference between the duration of a login request for a user with a password encoded in a non-default algorithm and the duration of a login request for a nonexistent user (which runs the default hasher). You may be able to mitigate this by *upgrading older password hashes*.

Passwords updates when changing the number of bcrypt rounds was added.

## Password upgrading without requiring a login

If you have an existing database with an older, weak hash such as MD5 or SHA1, you might want to upgrade those hashes yourself instead of waiting for the upgrade to happen when a user logs in (which may never happen if a user doesn't return to your site). In this case, you can use a "wrapped" password hasher.

For this example, we'll migrate a collection of SHA1 hashes to use PBKDF2(SHA1(password)) and add the corresponding password hasher for checking if a user entered the correct password on login. We assume we're using the built-in `User` model and that our project has an `accounts` app. You can modify the pattern to work with any algorithm or with a custom user model.

First, we'll add the custom hasher:

```
accounts/hashers.py

from django.contrib.auth.hashers import (
    PBKDF2PasswordHasher, SHA1PasswordHasher,
)

class PBKDF2WrappedSHA1PasswordHasher(PBKDF2PasswordHasher):
    algorithm = 'pbkdf2_wrapped_sha1'

    def encode_shal_hash(self, shal_hash, salt, iterations=None):
        return super(PBKDF2WrappedSHA1PasswordHasher, self).encode(shal_hash, salt, iterations)

    def encode(self, password, salt, iterations=None):
        _, _, shal_hash = SHA1PasswordHasher().encode(password, salt).split('$', 2)
        return self.encode_shal_hash(shal_hash, salt, iterations)
```

The data migration might look something like:

```
accounts/migrations/0002_migrate_shal_passwords.py

from django.db import migrations

from ..hashers import PBKDF2WrappedSHA1PasswordHasher

def forwards_func(apps, schema_editor):
    User = apps.get_model('auth', 'User')
    users = User.objects.filter(password__startswith='sha1$')
    hasher = PBKDF2WrappedSHA1PasswordHasher()
    for user in users:
        algorithm, salt, shal_hash = user.password.split('$', 2)
        user.password = hasher.encode_shal_hash(shal_hash, salt)
        user.save(update_fields=['password'])
```

```
class Migration(migrations.Migration):

    dependencies = [
        ('accounts', '0001_initial'),
        # replace this with the latest migration in contrib.auth
        ('auth', '####_migration_name'),
    ]

    operations = [
        migrations.RunPython(forwards_func),
    ]
```

Be aware that this migration will take on the order of several minutes for several thousand users, depending on the speed of your hardware.

Finally, we'll add a `PASSWORD_HASHERS` setting:

```
mysite/settings.py
```

```
PASSWORD_HASHERS = [
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',
    'accounts.hashers.PBKDF2WrappedSHA1PasswordHasher',
]
```

Include any other hashers that your site uses in this list.

### Included hashers

The full list of hashers included in Django is:

```
[
    'django.contrib.auth.hashers.PBKDF2PasswordHasher',
    'django.contrib.auth.hashers.PBKDF2SHA1PasswordHasher',
    'django.contrib.auth.hashers.Argon2PasswordHasher',
    'django.contrib.auth.hashers.BCryptSHA256PasswordHasher',
    'django.contrib.auth.hashers.BCryptPasswordHasher',
    'django.contrib.auth.hashers.SHA1PasswordHasher',
    'django.contrib.auth.hashers.MD5PasswordHasher',
    'django.contrib.auth.hashers.UnsaltedSHA1PasswordHasher',
    'django.contrib.auth.hashers.UnsaltedMD5PasswordHasher',
    'django.contrib.auth.hashers.CryptPasswordHasher',
]
```

The corresponding algorithm names are:

- pbkdf2\_sha256
- pbkdf2\_sha1
- argon2
- bcrypt\_sha256
- bcrypt
- sha1
- md5
- unsalted\_sha1

- `unsalted_md5`
- `crypt`

## Writing your own hasher

If you write your own password hasher that contains a work factor such as a number of iterations, you should implement a `harden_runtime(self, password, encoded)` method to bridge the runtime gap between the work factor supplied in the `encoded` password and the default work factor of the hasher. This prevents a user enumeration timing attack due to difference between a login request for a user with a password encoded in an older number of iterations and a nonexistent user (which runs the default hasher’s default number of iterations).

Taking PBKDF2 as example, if `encoded` contains 20,000 iterations and the hasher’s default `iterations` is 30,000, the method should run `password` through another 10,000 iterations of PBKDF2.

If your hasher doesn’t have a work factor, implement the method as a no-op (`pass`).

## Manually managing a user’s password

The `django.contrib.auth.hashers` module provides a set of functions to create and validate hashed password. You can use them independently from the `User` model.

**check\_password** (*password, encoded*)

If you’d like to manually authenticate a user by comparing a plain-text password to the hashed password in the database, use the convenience function `check_password()`. It takes two arguments: the plain-text password to check, and the full value of a user’s `password` field in the database to check against, and returns `True` if they match, `False` otherwise.

**make\_password** (*password, salt=None, hasher='default'*)

Creates a hashed password in the format used by this application. It takes one mandatory argument: the password in plain-text. Optionally, you can provide a salt and a hashing algorithm to use, if you don’t want to use the defaults (first entry of `PASSWORD_HASHERS` setting). See *Included hashers* for the algorithm name of each hasher. If the password argument is `None`, an unusable password is returned (a one that will be never accepted by `check_password()`).

**is\_password\_usable** (*encoded\_password*)

Checks if the given string is a hashed password that has a chance of being verified against `check_password()`.

## Password validation

Users often choose poor passwords. To help mitigate this problem, Django offers pluggable password validation. You can configure multiple password validators at the same time. A few validators are included in Django, but it’s simple to write your own as well.

Each password validator must provide a help text to explain the requirements to the user, validate a given password and return an error message if it does not meet the requirements, and optionally receive passwords that have been set. Validators can also have optional settings to fine tune their behavior.

Validation is controlled by the `AUTH_PASSWORD_VALIDATORS` setting. The default for the setting is an empty list, which means no validators are applied. In new projects created with the default `startproject` template, a simple set of validators is enabled.

By default, validators are used in the forms to reset or change passwords and in the `createsuperuser` and `changepassword` management commands. Validators aren’t applied at the model level, for example in `User`.

`objects.create_user()` and `create_superuser()`, because we assume that developers, not users, interact with Django at that level and also because model validation doesn't automatically run as part of creating models.

---

**Note:** Password validation can prevent the use of many types of weak passwords. However, the fact that a password passes all the validators doesn't guarantee that it is a strong password. There are many factors that can weaken a password that are not detectable by even the most advanced password validators.

---

## Enabling password validation

Password validation is configured in the `AUTH_PASSWORD_VALIDATORS` setting:

```
AUTH_PASSWORD_VALIDATORS = [
    {
        'NAME': 'django.contrib.auth.password_validation.
↪UserAttributeSimilarityValidator',
    },
    {
        'NAME': 'django.contrib.auth.password_validation.MinimumLengthValidator',
        'OPTIONS': {
            'min_length': 9,
        }
    },
    {
        'NAME': 'django.contrib.auth.password_validation.CommonPasswordValidator',
    },
    {
        'NAME': 'django.contrib.auth.password_validation.NumericPasswordValidator',
    },
]
```

This example enables all four included validators:

- `UserAttributeSimilarityValidator`, which checks the similarity between the password and a set of attributes of the user.
- `MinimumLengthValidator`, which simply checks whether the password meets a minimum length. This validator is configured with a custom option: it now requires the minimum length to be nine characters, instead of the default eight.
- `CommonPasswordValidator`, which checks whether the password occurs in a list of common passwords. By default, it compares to an included list of 1000 common passwords.
- `NumericPasswordValidator`, which checks whether the password isn't entirely numeric.

For `UserAttributeSimilarityValidator` and `CommonPasswordValidator`, we're simply using the default settings in this example. `NumericPasswordValidator` has no settings.

The help texts and any errors from password validators are always returned in the order they are listed in `AUTH_PASSWORD_VALIDATORS`.

## Included validators

Django includes four validators:

**class `MinimumLengthValidator`** (*min\_length=8*)

Validates whether the password meets a minimum length. The minimum length can be customized with the `min_length` parameter.

**class `UserAttributeSimilarityValidator`** (*user\_attributes=DEFAULT\_USER\_ATTRIBUTES, max\_similarity=0.7*)

Validates whether the password is sufficiently different from certain attributes of the user.

The `user_attributes` parameter should be an iterable of names of user attributes to compare to. If this argument is not provided, the default is used: `'username', 'first_name', 'last_name', 'email'`. Attributes that don't exist are ignored.

The maximum similarity the password can have, before it is rejected, can be set with the `max_similarity` parameter, on a scale of 0 to 1. A setting of 0 will cause all passwords to be rejected, whereas a setting of 1 will cause it to only reject passwords that are identical to an attribute's value.

**class `CommonPasswordValidator`** (*password\_list\_path=DEFAULT\_PASSWORD\_LIST\_PATH*)

Validates whether the password is not a common password. By default, this checks against a list of 1000 common password created by [Mark Burnett](#).

The `password_list_path` can be set to the path of a custom file of common passwords. This file should contain one password per line and may be plain text or gzipped.

**class `NumericPasswordValidator`**

Validates whether the password is not entirely numeric.

## Integrating validation

There are a few functions in `django.contrib.auth.password_validation` that you can call from your own forms or other code to integrate password validation. This can be useful if you use custom forms for password setting, or if you have API calls that allow passwords to be set, for example.

**`validate_password`** (*password, user=None, password\_validators=None*)

Validates a password. If all validators find the password valid, returns `None`. If one or more validators reject the password, raises a `ValidationError` with all the error messages from the validators.

The `user` object is optional: if it's not provided, some validators may not be able to perform any validation and will accept any password.

**`password_changed`** (*password, user=None, password\_validators=None*)

Informs all validators that the password has been changed. This can be used by validators such as one that prevents password reuse. This should be called once the password has been successfully changed.

For subclasses of `AbstractBaseUser`, the password field will be marked as “dirty” when calling `set_password()` which triggers a call to `password_changed()` after the user is saved.

**`password_validators_help_texts`** (*password\_validators=None*)

Returns a list of the help texts of all validators. These explain the password requirements to the user.

**`password_validators_help_text_html`** (*password\_validators=None*)

Returns an HTML string with all help texts in an `<ul>`. This is helpful when adding password validation to forms, as you can pass the output directly to the `help_text` parameter of a form field.

**`get_password_validators`** (*validator\_config*)

Returns a set of validator objects based on the `validator_config` parameter. By default, all functions use the validators defined in `AUTH_PASSWORD_VALIDATORS`, but by calling this function with an alternate set of validators and then passing the result into the `password_validators` parameter of the other functions, your custom set of validators will be used instead. This is useful when you have a typical set of validators to use for most scenarios, but also have a special situation that requires a custom set. If you always use the same set of

validators, there is no need to use this function, as the configuration from `AUTH_PASSWORD_VALIDATORS` is used by default.

The structure of `validator_config` is identical to the structure of `AUTH_PASSWORD_VALIDATORS`. The return value of this function can be passed into the `password_validators` parameter of the functions listed above.

Note that where the password is passed to one of these functions, this should always be the clear text password - not a hashed password.

## Writing your own validator

If Django's built-in validators are not sufficient, you can write your own password validators. Validators are fairly simple classes. They must implement two methods:

- `validate(self, password, user=None)`: validate a password. Return `None` if the password is valid, or raise a `ValidationError` with an error message if the password is not valid. You must be able to deal with `user` being `None` - if that means your validator can't run, simply return `None` for no error.
- `get_help_text()`: provide a help text to explain the requirements to the user.

Any items in the `OPTIONS` in `AUTH_PASSWORD_VALIDATORS` for your validator will be passed to the constructor. All constructor arguments should have a default value.

Here's a basic example of a validator, with one optional setting:

```
from django.core.exceptions import ValidationError
from django.utils.translation import ugettext as _

class MinimumLengthValidator(object):
    def __init__(self, min_length=8):
        self.min_length = min_length

    def validate(self, password, user=None):
        if len(password) < self.min_length:
            raise ValidationError(
                _("This password must contain at least %(min_length)d characters."),
                code='password_too_short',
                params={'min_length': self.min_length},
            )

    def get_help_text(self):
        return _("Your password must contain at least %(min_length)d characters."
                % {'min_length': self.min_length})
```

You can also implement `password_changed(password, user=None)`, which will be called after a successful password change. That can be used to prevent password reuse, for example. However, if you decide to store a user's previous passwords, you should never do so in clear text.

## 3.10.3 Customizing authentication in Django

The authentication that comes with Django is good enough for most common cases, but you may have needs not met by the out-of-the-box defaults. To customize authentication to your projects needs involves understanding what points of the provided system are extensible or replaceable. This document provides details about how the auth system can be customized.

*Authentication backends* provide an extensible system for when a username and password stored with the user model need to be authenticated against a different service than Django’s default.

You can give your models *custom permissions* that can be checked through Django’s authorization system.

You can *extend* the default `User` model, or *substitute* a completely customized model.

## Other authentication sources

There may be times you have the need to hook into another authentication source – that is, another source of usernames and passwords or authentication methods.

For example, your company may already have an LDAP setup that stores a username and password for every employee. It’d be a hassle for both the network administrator and the users themselves if users had separate accounts in LDAP and the Django-based applications.

So, to handle situations like this, the Django authentication system lets you plug in other authentication sources. You can override Django’s default database-based scheme, or you can use the default system in tandem with other systems.

See the *authentication backend reference* for information on the authentication backends included with Django.

## Specifying authentication backends

Behind the scenes, Django maintains a list of “authentication backends” that it checks for authentication. When somebody calls `django.contrib.auth.authenticate()` – as described in *How to log a user in* – Django tries authenticating across all of its authentication backends. If the first authentication method fails, Django tries the second one, and so on, until all backends have been attempted.

The list of authentication backends to use is specified in the `AUTHENTICATION_BACKENDS` setting. This should be a list of Python path names that point to Python classes that know how to authenticate. These classes can be anywhere on your Python path.

By default, `AUTHENTICATION_BACKENDS` is set to:

```
['django.contrib.auth.backends.ModelBackend']
```

That’s the basic authentication backend that checks the Django users database and queries the built-in permissions. It does not provide protection against brute force attacks via any rate limiting mechanism. You may either implement your own rate limiting mechanism in a custom auth backend, or use the mechanisms provided by most Web servers.

The order of `AUTHENTICATION_BACKENDS` matters, so if the same username and password is valid in multiple backends, Django will stop processing at the first positive match.

If a backend raises a `PermissionDenied` exception, authentication will immediately fail. Django won’t check the backends that follow.

---

**Note:** Once a user has authenticated, Django stores which backend was used to authenticate the user in the user’s session, and re-uses the same backend for the duration of that session whenever access to the currently authenticated user is needed. This effectively means that authentication sources are cached on a per-session basis, so if you change `AUTHENTICATION_BACKENDS`, you’ll need to clear out session data if you need to force users to re-authenticate using different methods. A simple way to do that is simply to execute `Session.objects.all().delete()`.

---

## Writing an authentication backend

An authentication backend is a class that implements two required methods: `get_user(user_id)` and `authenticate(**credentials)`, as well as a set of optional permission related [authorization methods](#).

The `get_user` method takes a `user_id` – which could be a username, database ID or whatever, but has to be the primary key of your user object – and returns a user object.

The `authenticate` method takes credentials as keyword arguments. Most of the time, it'll just look like this:

```
class MyBackend(object):
    def authenticate(self, username=None, password=None):
        # Check the username/password and return a user.
        ...
```

But it could also authenticate a token, like so:

```
class MyBackend(object):
    def authenticate(self, token=None):
        # Check the token and return a user.
        ...
```

Either way, `authenticate()` should check the credentials it gets and return a user object that matches those credentials if the credentials are valid. If they're not valid, it should return `None`.

The Django admin is tightly coupled to the Django [User object](#). The best way to deal with this is to create a Django User object for each user that exists for your backend (e.g., in your LDAP directory, your external SQL database, etc.) You can either write a script to do this in advance, or your `authenticate` method can do it the first time a user logs in.

Here's an example backend that authenticates against a username and password variable defined in your `settings.py` file and creates a Django User object the first time a user authenticates:

```
from django.conf import settings
from django.contrib.auth.hashers import check_password
from django.contrib.auth.models import User

class SettingsBackend(object):
    """
    Authenticate against the settings ADMIN_LOGIN and ADMIN_PASSWORD.

    Use the login name and a hash of the password. For example:

    ADMIN_LOGIN = 'admin'
    ADMIN_PASSWORD = 'pbkdf2_sha256$30000$Vo0VlMnkr4Bk$qEvdtyZRWTcOsCnI/
    ↪oQ7fVOu1XAURIZYoOZ3iq8Dr4M='
    """

    def authenticate(self, username=None, password=None):
        login_valid = (settings.ADMIN_LOGIN == username)
        pwd_valid = check_password(password, settings.ADMIN_PASSWORD)
        if login_valid and pwd_valid:
            try:
                user = User.objects.get(username=username)
            except User.DoesNotExist:
                # Create a new user. There's no need to set a password
                # because only the password from settings.py is checked.
                user = User(username=username)
                user.is_staff = True
```

```

        user.is_superuser = True
        user.save()
    return user
return None

def get_user(self, user_id):
    try:
        return User.objects.get(pk=user_id)
    except User.DoesNotExist:
        return None

```

## Handling authorization in custom backends

Custom auth backends can provide their own permissions.

The user model will delegate permission lookup functions (*get\_group\_permissions()*, *get\_all\_permissions()*, *has\_perm()*, and *has\_module\_perms()*) to any authentication backend that implements these functions.

The permissions given to the user will be the superset of all permissions returned by all backends. That is, Django grants a permission to a user that any one backend grants.

If a backend raises a *PermissionDenied* exception in *has\_perm()* or *has\_module\_perms()*, the authorization will immediately fail and Django won't check the backends that follow.

The simple backend above could implement permissions for the magic admin fairly simply:

```

class SettingsBackend(object):
    ...
    def has_perm(self, user_obj, perm, obj=None):
        return user_obj.username == settings.ADMIN_LOGIN

```

This gives full permissions to the user granted access in the above example. Notice that in addition to the same arguments given to the associated *django.contrib.auth.models.User* functions, the backend auth functions all take the user object, which may be an anonymous user, as an argument.

A full authorization implementation can be found in the *ModelBackend* class in *django/contrib/auth/backends.py*, which is the default backend and queries the *auth\_permission* table most of the time. If you wish to provide custom behavior for only part of the backend API, you can take advantage of Python inheritance and subclass *ModelBackend* instead of implementing the complete API in a custom backend.

## Authorization for anonymous users

An anonymous user is one that is not authenticated i.e. they have provided no valid authentication details. However, that does not necessarily mean they are not authorized to do anything. At the most basic level, most websites authorize anonymous users to browse most of the site, and many allow anonymous posting of comments etc.

Django's permission framework does not have a place to store permissions for anonymous users. However, the user object passed to an authentication backend may be an *django.contrib.auth.models.AnonymousUser* object, allowing the backend to specify custom authorization behavior for anonymous users. This is especially useful for the authors of re-usable apps, who can delegate all questions of authorization to the auth backend, rather than needing settings, for example, to control anonymous access.

## Authorization for inactive users

An inactive user is one that has its `is_active` field set to `False`. The `ModelBackend` and `RemoteUserBackend` authentication backends prohibits these users from authenticating. If a custom user model doesn't have an `is_active` field, all users will be allowed to authenticate.

You can use `AllowAllUsersModelBackend` or `AllowAllUsersRemoteUserBackend` if you want to allow inactive users to authenticate.

The support for anonymous users in the permission system allows for a scenario where anonymous users have permissions to do something while inactive authenticated users do not.

Do not forget to test for the `is_active` attribute of the user in your own backend permission methods.

In older versions, the `ModelBackend` allowed inactive users to authenticate.

## Handling object permissions

Django's permission framework has a foundation for object permissions, though there is no implementation for it in the core. That means that checking for object permissions will always return `False` or an empty list (depending on the check performed). An authentication backend will receive the keyword parameters `obj` and `user_obj` for each object related authorization method and can return the object level permission as appropriate.

## Custom permissions

To create custom permissions for a given model object, use the `permissions` *model Meta attribute*.

This example `Task` model creates three custom permissions, i.e., actions users can or cannot do with `Task` instances, specific to your application:

```
class Task(models.Model):
    ...
    class Meta:
        permissions = (
            ("view_task", "Can see available tasks"),
            ("change_task_status", "Can change the status of tasks"),
            ("close_task", "Can remove a task by setting its status as closed"),
        )
```

The only thing this does is create those extra permissions when you run `manage.py migrate` (the function that creates permissions is connected to the `post_migrate` signal). Your code is in charge of checking the value of these permissions when a user is trying to access the functionality provided by the application (viewing tasks, changing the status of tasks, closing tasks.) Continuing the above example, the following checks if a user may view tasks:

```
user.has_perm('app.view_task')
```

## Extending the existing `User` model

There are two ways to extend the default `User` model without substituting your own model. If the changes you need are purely behavioral, and don't require any change to what is stored in the database, you can create a *proxy model* based on `User`. This allows for any of the features offered by proxy models including default ordering, custom managers, or custom model methods.

If you wish to store information related to `User`, you can use a `OneToOneField` to a model containing the fields for additional information. This one-to-one model is often called a profile model, as it might store non-auth related information about a site user. For example you might create an `Employee` model:

```
from django.contrib.auth.models import User

class Employee(models.Model):
    user = models.OneToOneField(User, on_delete=models.CASCADE)
    department = models.CharField(max_length=100)
```

Assuming an existing `Employee` Fred Smith who has both a `User` and `Employee` model, you can access the related information using Django's standard related model conventions:

```
>>> u = User.objects.get(username='fsmith')
>>> fred's_department = u.employee.department
```

To add a profile model's fields to the user page in the admin, define an `InlineModelAdmin` (for this example, we'll use a `StackedInline`) in your app's `admin.py` and add it to a `UserAdmin` class which is registered with the `User` class:

```
from django.contrib import admin
from django.contrib.auth.admin import UserAdmin as BaseUserAdmin
from django.contrib.auth.models import User

from my_user_profile_app.models import Employee

# Define an inline admin descriptor for Employee model
# which acts a bit like a singleton
class EmployeeInline(admin.StackedInline):
    model = Employee
    can_delete = False
    verbose_name_plural = 'employee'

# Define a new User admin
class UserAdmin(BaseUserAdmin):
    inlines = (EmployeeInline, )

# Re-register UserAdmin
admin.site.unregister(User)
admin.site.register(User, UserAdmin)
```

These profile models are not special in any way - they are just Django models that happen to have a one-to-one link with a user model. As such, they aren't auto created when a user is created, but a `django.db.models.signals.post_save` could be used to create or update related models as appropriate.

Using related models results in additional queries or joins to retrieve the related data. Depending on your needs, a custom user model that includes the related fields may be your better option, however, existing relations to the default user model within your project's apps may justify the extra database load.

### Substituting a custom `User` model

Some kinds of projects may have authentication requirements for which Django's built-in `User` model is not always appropriate. For instance, on some sites it makes more sense to use an email address as your identification token instead of a username.

Django allows you to override the default user model by providing a value for the `AUTH_USER_MODEL` setting that references a custom model:

```
AUTH_USER_MODEL = 'myapp.MyUser'
```

This dotted pair describes the name of the Django app (which must be in your `INSTALLED_APPS`), and the name of the Django model that you wish to use as your user model.

### Using a custom user model when starting a project

If you're starting a new project, it's highly recommended to set up a custom user model, even if the default `User` model is sufficient for you. This model behaves identically to the default user model, but you'll be able to customize it in the future if the need arises:

```
from django.contrib.auth.models import AbstractUser

class User(AbstractUser):
    pass
```

Don't forget to point `AUTH_USER_MODEL` to it. Do this before creating any migrations or running `manage.py migrate` for the first time.

### Changing to a custom user model mid-project

Changing `AUTH_USER_MODEL` after you've created database tables is significantly more difficult since it affects foreign keys and many-to-many relationships, for example.

This change can't be done automatically and requires manually fixing your schema, moving your data from the old user table, and possibly manually reapplying some migrations. See [#25313](#) for an outline of the steps.

Due to limitations of Django's dynamic dependency feature for swappable models, the model referenced by `AUTH_USER_MODEL` must be created in the first migration of its app (usually called `0001_initial`); otherwise, you'll have dependency issues.

In addition, you may run into a `CircularDependencyError` when running your migrations as Django won't be able to automatically break the dependency loop due to the dynamic dependency. If you see this error, you should break the loop by moving the models depended on by your user model into a second migration. (You can try making two normal models that have a `ForeignKey` to each other and seeing how `makemigrations` resolves that circular dependency if you want to see how it's usually done.)

### Reusable apps and `AUTH_USER_MODEL`

Reusable apps shouldn't implement a custom user model. A project may use many apps, and two reusable apps that implemented a custom user model couldn't be used together. If you need to store per user information in your app, use a `ForeignKey` or `OneToOneField` to `settings.AUTH_USER_MODEL` as described below.

### Referencing the `User` model

If you reference `User` directly (for example, by referring to it in a foreign key), your code will not work in projects where the `AUTH_USER_MODEL` setting has been changed to a different user model.

#### `get_user_model()`

Instead of referring to `User` directly, you should reference the user model using `django.contrib.auth.get_user_model()`. This method will return the currently active user model – the custom user model if one is specified, or `User` otherwise.

When you define a foreign key or many-to-many relations to the user model, you should specify the custom model using the `AUTH_USER_MODEL` setting. For example:

```
from django.conf import settings
from django.db import models

class Article(models.Model):
    author = models.ForeignKey(
        settings.AUTH_USER_MODEL,
        on_delete=models.CASCADE,
    )
```

When connecting to signals sent by the user model, you should specify the custom model using the `AUTH_USER_MODEL` setting. For example:

```
from django.conf import settings
from django.db.models.signals import post_save

def post_save_receiver(sender, instance, created, **kwargs):
    pass

post_save.connect(post_save_receiver, sender=settings.AUTH_USER_MODEL)
```

Generally speaking, you should reference the user model with the `AUTH_USER_MODEL` setting in code that is executed at import time. `get_user_model()` only works once Django has imported all models.

## Specifying a custom user model

### Model design considerations

Think carefully before handling information not directly related to authentication in your custom user model.

It may be better to store app-specific user information in a model that has a relation with the user model. That allows each app to specify its own user data requirements without risking conflicts with other apps. On the other hand, queries to retrieve this related information will involve a database join, which may have an effect on performance.

Django expects your custom user model to meet some minimum requirements.

1. If you use the default authentication backend, then your model must have a single unique field that can be used for identification purposes. This can be a username, an email address, or any other unique attribute. A non-unique username field is allowed if you use a custom authentication backend that can support it.
2. Your model must provide a way to address the user in a “short” and “long” form. The most common interpretation of this would be to use the user’s given name as the “short” identifier, and the user’s full name as the “long” identifier. However, there are no constraints on what these two methods return - if you want, they can return exactly the same value.

The easiest way to construct a compliant custom user model is to inherit from `AbstractBaseUser`. `AbstractBaseUser` provides the core implementation of a user model, including hashed passwords and tokenized password resets. You must then provide some key implementation details:

```
class models.CustomUser
```

#### `USERNAME_FIELD`

A string describing the name of the field on the user model that is used as the unique identifier. This will usually be a username of some kind, but it can also be an email address, or any other unique identifier. The

field *must* be unique (i.e., have `unique=True` set in its definition), unless you use a custom authentication backend that can support non-unique usernames.

In the following example, the field `identifier` is used as the identifying field:

```
class MyUser(AbstractBaseUser):
    identifier = models.CharField(max_length=40, unique=True)
    ...
    USERNAME_FIELD = 'identifier'
```

`USERNAME_FIELD` now supports *ForeignKeys*. Since there is no way to pass model instances during the `createsuperuser` prompt, expect the user to enter the value of `to_field` value (the *primary\_key* by default) of an existing instance.

### REQUIRED\_FIELDS

A list of the field names that will be prompted for when creating a user via the `createsuperuser` management command. The user will be prompted to supply a value for each of these fields. It must include any field for which `blank` is `False` or undefined and may include additional fields you want prompted for when a user is created interactively. `REQUIRED_FIELDS` has no effect in other parts of Django, like creating a user in the admin.

For example, here is the partial definition for a user model that defines two required fields - a date of birth and height:

```
class MyUser(AbstractBaseUser):
    ...
    date_of_birth = models.DateField()
    height = models.FloatField()
    ...
    REQUIRED_FIELDS = ['date_of_birth', 'height']
```

---

**Note:** `REQUIRED_FIELDS` must contain all required fields on your user model, but should *not* contain the `USERNAME_FIELD` or `password` as these fields will always be prompted for.

---

`REQUIRED_FIELDS` now supports *ForeignKeys*. Since there is no way to pass model instances during the `createsuperuser` prompt, expect the user to enter the value of `to_field` value (the *primary\_key* by default) of an existing instance.

### `is_active`

A boolean attribute that indicates whether the user is considered “active”. This attribute is provided as an attribute on `AbstractBaseUser` defaulting to `True`. How you choose to implement it will depend on the details of your chosen auth backends. See the documentation of the *is\_active attribute on the built-in user model* for details.

### `get_full_name()`

A longer formal identifier for the user. A common interpretation would be the full name of the user, but it can be any string that identifies the user.

### `get_short_name()`

A short, informal identifier for the user. A common interpretation would be the first name of the user, but it can be any string that identifies the user in an informal way. It may also return the same value as `django.contrib.auth.models.User.get_full_name()`.

---

### Importing `AbstractBaseUser`

`AbstractBaseUser` and `BaseUserManager` are importable from `django.contrib.auth.base_user` so that they can be imported without including `django.contrib.auth` in

*INSTALLED\_APPS* (this raised a deprecation warning in older versions and is no longer supported in Django 1.9).

The following attributes and methods are available on any subclass of *AbstractBaseUser*:

**class** `models.AbstractBaseUser`

**get\_username()**

Returns the value of the field nominated by `USERNAME_FIELD`.

**clean()**

Normalizes the username by calling *normalize\_username()*. If you override this method, be sure to call *super()* to retain the normalization.

**classmethod** `normalize_username(username)`

Applies NFKC Unicode normalization to usernames so that visually identical characters with different Unicode code points are considered identical.

**is\_authenticated**

Read-only attribute which is always `True` (as opposed to `AnonymousUser.is_authenticated` which is always `False`). This is a way to tell if the user has been authenticated. This does not imply any permissions and doesn't check if the user is active or has a valid session. Even though normally you will check this attribute on `request.user` to find out whether it has been populated by the *AuthenticationMiddleware* (representing the currently logged-in user), you should know this attribute is `True` for any *User* instance.

In older versions, this was a method. Backwards-compatibility support for using it as a method will be removed in Django 2.0.

**is\_anonymous**

Read-only attribute which is always `False`. This is a way of differentiating *User* and *AnonymousUser* objects. Generally, you should prefer using *is\_authenticated* to this attribute.

In older versions, this was a method. Backwards-compatibility support for using it as a method will be removed in Django 2.0.

**set\_password(raw\_password)**

Sets the user's password to the given raw string, taking care of the password hashing. Doesn't save the *AbstractBaseUser* object.

When the `raw_password` is `None`, the password will be set to an unusable password, as if *set\_unusable\_password()* were used.

**check\_password(raw\_password)**

Returns `True` if the given raw string is the correct password for the user. (This takes care of the password hashing in making the comparison.)

**set\_unusable\_password()**

Marks the user as having no password set. This isn't the same as having a blank string for a password. *check\_password()* for this user will never return `True`. Doesn't save the *AbstractBaseUser* object.

You may need this if authentication for your application takes place against an existing external source such as an LDAP directory.

**has\_usable\_password()**

Returns `False` if *set\_unusable\_password()* has been called for this user.

**get\_session\_auth\_hash()**

Returns an HMAC of the password field. Used for *Session invalidation on password change*.

You should also define a custom manager for your user model. If your user model defines `username`, `email`, `is_staff`, `is_active`, `is_superuser`, `last_login`, and `date_joined` fields the same as Django's default user, you can just install Django's `UserManager`; however, if your user model defines different fields, you'll need to define a custom manager that extends `BaseUserManager` providing two additional methods:

```
class models.CustomUserManager
```

```
    create_user(*username_field*, password=None, **other_fields)
```

The prototype of `create_user()` should accept the username field, plus all required fields as arguments. For example, if your user model uses `email` as the username field, and has `date_of_birth` as a required field, then `create_user` should be defined as:

```
def create_user(self, email, date_of_birth, password=None):
    # create user here
    ...
```

```
    create_superuser(*username_field*, password, **other_fields)
```

The prototype of `create_superuser()` should accept the username field, plus all required fields as arguments. For example, if your user model uses `email` as the username field, and has `date_of_birth` as a required field, then `create_superuser` should be defined as:

```
def create_superuser(self, email, date_of_birth, password):
    # create superuser here
    ...
```

Unlike `create_user()`, `create_superuser()` *must* require the caller to provide a password.

`BaseUserManager` provides the following utility methods:

```
class models.BaseUserManager
```

```
    classmethod normalize_email(email)
```

Normalizes email addresses by lowercasing the domain portion of the email address.

```
    get_by_natural_key(username)
```

Retrieves a user instance using the contents of the field nominated by `USERNAME_FIELD`.

```
    make_random_password(length=10, allowed_chars='abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ23456789')
```

Returns a random password with the given length and given string of allowed characters. Note that the default value of `allowed_chars` doesn't contain letters that can cause user confusion, including:

- `i`, `l`, `I`, and `1` (lowercase letter `i`, lowercase letter `L`, uppercase letter `i`, and the number one)
- `o`, `O`, and `0` (lowercase letter `o`, uppercase letter `o`, and zero)

## Extending Django's default User

If you're entirely happy with Django's `User` model and you just want to add some additional profile information, you could simply subclass `django.contrib.auth.models.AbstractUser` and add your custom profile fields, although we'd recommend a separate model as described in the "Model design considerations" note of *Specifying a custom user model*. `AbstractUser` provides the full implementation of the default `User` as an *abstract model*.

## Custom users and the built-in auth forms

Django's built-in *forms* and *views* make certain assumptions about the user model that they are working with.

The following forms are compatible with any subclass of *AbstractBaseUser*:

- *AuthenticationForm*: Uses the username field specified by *USERNAME\_FIELD*.
- *SetPasswordForm*
- *PasswordChangeForm*
- *AdminPasswordChangeForm*

The following forms make assumptions about the user model and can be used as-is if those assumptions are met:

- *PasswordResetForm*: Assumes that the user model has a field named *email* that can be used to identify the user and a boolean field named *is\_active* to prevent password resets for inactive users.

Finally, the following forms are tied to *User* and need to be rewritten or extended to work with a custom user model:

- *UserCreationForm*
- *UserChangeForm*

If your custom user model is a simple subclass of *AbstractUser*, then you can extend these forms in this manner:

```
from django.contrib.auth.forms import UserCreationForm
from myapp.models import CustomUser

class CustomUserCreationForm(UserCreationForm):

    class Meta(UserCreationForm.Meta):
        model = CustomUser
        fields = UserCreationForm.Meta.fields + ('custom_field',)
```

### Custom users and `django.contrib.admin`

If you want your custom user model to also work with the admin, your user model must define some additional attributes and methods. These methods allow the admin to control access of the user to admin content:

```
class models.CustomUser
```

```
is_staff
```

Returns True if the user is allowed to have access to the admin site.

```
is_active
```

Returns True if the user account is currently active.

```
has_perm(perm, obj=None):
```

Returns True if the user has the named permission. If *obj* is provided, the permission needs to be checked against a specific object instance.

```
has_module_perms(app_label):
```

Returns True if the user has permission to access models in the given app.

You will also need to register your custom user model with the admin. If your custom user model extends `django.contrib.auth.models.AbstractUser`, you can use Django's existing `django.contrib.auth.admin.UserAdmin` class. However, if your user model extends *AbstractBaseUser*, you'll need to define a custom `ModelAdmin` class. It may be possible to subclass the default `django.contrib.auth.admin.UserAdmin`; however, you'll need to override any of the definitions that refer to fields on `django.contrib.auth.models.AbstractUser` that aren't on your custom user class.

## Custom users and permissions

To make it easy to include Django's permission framework into your own user class, Django provides *PermissionsMixin*. This is an abstract model you can include in the class hierarchy for your user model, giving you all the methods and database fields necessary to support Django's permission model.

*PermissionsMixin* provides the following methods and attributes:

**class** `models.PermissionsMixin`

### **is\_superuser**

Boolean. Designates that this user has all permissions without explicitly assigning them.

### **get\_group\_permissions** (*obj=None*)

Returns a set of permission strings that the user has, through their groups.

If *obj* is passed in, only returns the group permissions for this specific object.

### **get\_all\_permissions** (*obj=None*)

Returns a set of permission strings that the user has, both through group and user permissions.

If *obj* is passed in, only returns the permissions for this specific object.

### **has\_perm** (*perm, obj=None*)

Returns `True` if the user has the specified permission, where *perm* is in the format "`<app label>.<permission codename>`" (see *permissions*). If the user is inactive, this method will always return `False`.

If *obj* is passed in, this method won't check for a permission for the model, but for this specific object.

### **has\_perms** (*perm\_list, obj=None*)

Returns `True` if the user has each of the specified permissions, where each *perm* is in the format "`<app label>.<permission codename>`". If the user is inactive, this method will always return `False`.

If *obj* is passed in, this method won't check for permissions for the model, but for the specific object.

### **has\_module\_perms** (*package\_name*)

Returns `True` if the user has any permissions in the given package (the Django app label). If the user is inactive, this method will always return `False`.

---

## PermissionsMixin and ModelBackend

If you don't include the *PermissionsMixin*, you must ensure you don't invoke the permissions methods on *ModelBackend*. *ModelBackend* assumes that certain fields are available on your user model. If your user model doesn't provide those fields, you'll receive database errors when you check permissions.

---

## Custom users and proxy models

One limitation of custom user models is that installing a custom user model will break any proxy model extending *User*. Proxy models must be based on a concrete base class; by defining a custom user model, you remove the ability of Django to reliably identify the base class.

If your project uses proxy models, you must either modify the proxy to extend the user model that's in use in your project, or merge your proxy's behavior into your *User* subclass.

## A full example

Here is an example of an admin-compliant custom user app. This user model uses an email address as the username, and has a required date of birth; it provides no permission checking, beyond a simple `admin` flag on the user account. This model would be compatible with all the built-in auth forms and views, except for the user creation forms. This example illustrates how most of the components work together, but is not intended to be copied directly into projects for production use.

This code would all live in a `models.py` file for a custom authentication app:

```

from django.db import models
from django.contrib.auth.models import (
    BaseUserManager, AbstractBaseUser
)

class MyUserManager(BaseUserManager):
    def create_user(self, email, date_of_birth, password=None):
        """
        Creates and saves a User with the given email, date of
        birth and password.
        """
        if not email:
            raise ValueError('Users must have an email address')

        user = self.model(
            email=self.normalize_email(email),
            date_of_birth=date_of_birth,
        )

        user.set_password(password)
        user.save(using=self._db)
        return user

    def create_superuser(self, email, date_of_birth, password):
        """
        Creates and saves a superuser with the given email, date of
        birth and password.
        """
        user = self.create_user(
            email,
            password=password,
            date_of_birth=date_of_birth,
        )
        user.is_admin = True
        user.save(using=self._db)
        return user

class MyUser(AbstractBaseUser):
    email = models.EmailField(
        verbose_name='email address',
        max_length=255,
        unique=True,
    )
    date_of_birth = models.DateField()
    is_active = models.BooleanField(default=True)
    is_admin = models.BooleanField(default=False)

```

```
objects = MyUserManager()

USERNAME_FIELD = 'email'
REQUIRED_FIELDS = ['date_of_birth']

def get_full_name(self):
    # The user is identified by their email address
    return self.email

def get_short_name(self):
    # The user is identified by their email address
    return self.email

def __str__(self):
    # __unicode__ on Python 2
    return self.email

def has_perm(self, perm, obj=None):
    "Does the user have a specific permission?"
    # Simplest possible answer: Yes, always
    return True

def has_module_perms(self, app_label):
    "Does the user have permissions to view the app `app_label`?"
    # Simplest possible answer: Yes, always
    return True

@property
def is_staff(self):
    "Is the user a member of staff?"
    # Simplest possible answer: All admins are staff
    return self.is_admin
```

Then, to register this custom user model with Django's admin, the following code would be required in the app's `admin.py` file:

```
from django import forms
from django.contrib import admin
from django.contrib.auth.models import Group
from django.contrib.auth.admin import UserAdmin as BaseUserAdmin
from django.contrib.auth.forms import ReadOnlyPasswordHashField

from customauth.models import MyUser

class UserCreationForm(forms.ModelForm):
    """A form for creating new users. Includes all the required
    fields, plus a repeated password."""
    password1 = forms.CharField(label='Password', widget=forms.PasswordInput)
    password2 = forms.CharField(label='Password confirmation', widget=forms.
↪PasswordInput)

    class Meta:
        model = MyUser
        fields = ('email', 'date_of_birth')

    def clean_password2(self):
        # Check that the two password entries match
```

```

password1 = self.cleaned_data.get("password1")
password2 = self.cleaned_data.get("password2")
if password1 and password2 and password1 != password2:
    raise forms.ValidationError("Passwords don't match")
return password2

def save(self, commit=True):
    # Save the provided password in hashed format
    user = super(UserCreationForm, self).save(commit=False)
    user.set_password(self.cleaned_data["password1"])
    if commit:
        user.save()
    return user

class UserChangeForm(forms.ModelForm):
    """A form for updating users. Includes all the fields on
    the user, but replaces the password field with admin's
    password hash display field.
    """
    password = ReadOnlyPasswordHashField()

    class Meta:
        model = MyUser
        fields = ('email', 'password', 'date_of_birth', 'is_active', 'is_admin')

    def clean_password(self):
        # Regardless of what the user provides, return the initial value.
        # This is done here, rather than on the field, because the
        # field does not have access to the initial value
        return self.initial["password"]

class UserAdmin(BaseUserAdmin):
    # The forms to add and change user instances
    form = UserChangeForm
    add_form = UserCreationForm

    # The fields to be used in displaying the User model.
    # These override the definitions on the base UserAdmin
    # that reference specific fields on auth.User.
    list_display = ('email', 'date_of_birth', 'is_admin')
    list_filter = ('is_admin',)
    fieldsets = (
        (None, {'fields': ('email', 'password')}),
        ('Personal info', {'fields': ('date_of_birth',)}),
        ('Permissions', {'fields': ('is_admin',)}),
    )
    # add_fieldsets is not a standard ModelAdmin attribute. UserAdmin
    # overrides get_fieldsets to use this attribute when creating a user.
    add_fieldsets = (
        (None, {
            'classes': ('wide',),
            'fields': ('email', 'date_of_birth', 'password1', 'password2')
        }),
    )
    search_fields = ('email',)
    ordering = ('email',)

```

```
filter_horizontal = ()

# Now register the new UserAdmin...
admin.site.register(MyUser, UserAdmin)
# ... and, since we're not using Django's built-in permissions,
# unregister the Group model from admin.
admin.site.unregister(Group)
```

Finally, specify the custom model as the default user model for your project using the `AUTH_USER_MODEL` setting in your `settings.py`:

```
AUTH_USER_MODEL = 'customauth.MyUser'
```

Django comes with a user authentication system. It handles user accounts, groups, permissions and cookie-based user sessions. This section of the documentation explains how the default implementation works out of the box, as well as how to *extend and customize* it to suit your project's needs.

### 3.10.4 Overview

The Django authentication system handles both authentication and authorization. Briefly, authentication verifies a user is who they claim to be, and authorization determines what an authenticated user is allowed to do. Here the term authentication is used to refer to both tasks.

The auth system consists of:

- Users
- Permissions: Binary (yes/no) flags designating whether a user may perform a certain task.
- Groups: A generic way of applying labels and permissions to more than one user.
- A configurable password hashing system
- Forms and view tools for logging in users, or restricting content
- A pluggable backend system

The authentication system in Django aims to be very generic and doesn't provide some features commonly found in web authentication systems. Solutions for some of these common problems have been implemented in third-party packages:

- Password strength checking
- Throttling of login attempts
- Authentication against third-parties (OAuth, for example)

### 3.10.5 Installation

Authentication support is bundled as a Django contrib module in `django.contrib.auth`. By default, the required configuration is already included in the `settings.py` generated by `django-admin startproject`, these consist of two items listed in your `INSTALLED_APPS` setting:

1. `'django.contrib.auth'` contains the core of the authentication framework, and its default models.
2. `'django.contrib.contenttypes'` is the Django *content type system*, which allows permissions to be associated with models you create.

and these items in your `MIDDLEWARE` setting:

1. `SessionMiddleware` manages *sessions* across requests.
2. `AuthenticationMiddleware` associates users with requests using sessions.

With these settings in place, running the command `manage.py migrate` creates the necessary database tables for auth related models and permissions for any models defined in your installed apps.

### 3.10.6 Usage

*Using Django’s default implementation*

- *Working with User objects*
- *Permissions and authorization*
- *Authentication in web requests*
- *Managing users in the admin*

*API reference for the default implementation*

*Customizing Users and authentication*

*Password management in Django*

## 3.11 Django’s cache framework

A fundamental trade-off in dynamic websites is, well, they’re dynamic. Each time a user requests a page, the Web server makes all sorts of calculations – from database queries to template rendering to business logic – to create the page that your site’s visitor sees. This is a lot more expensive, from a processing-overhead perspective, than your standard read-a-file-off-the-filesystem server arrangement.

For most Web applications, this overhead isn’t a big deal. Most Web applications aren’t `washingtonpost.com` or `slashdot.org`; they’re simply small- to medium-sized sites with so-so traffic. But for medium- to high-traffic sites, it’s essential to cut as much overhead as possible.

That’s where caching comes in.

To cache something is to save the result of an expensive calculation so that you don’t have to perform the calculation next time. Here’s some pseudocode explaining how this would work for a dynamically generated Web page:

```
given a URL, try finding that page in the cache
if the page is in the cache:
    return the cached page
else:
    generate the page
    save the generated page in the cache (for next time)
    return the generated page
```

Django comes with a robust cache system that lets you save dynamic pages so they don’t have to be calculated for each request. For convenience, Django offers different levels of cache granularity: You can cache the output of specific views, you can cache only the pieces that are difficult to produce, or you can cache your entire site.

Django also works well with “downstream” caches, such as [Squid](#) and browser-based caches. These are the types of caches that you don’t directly control but to which you can provide hints (via HTTP headers) about which parts of your site should be cached, and how.

**See also:**

The *Cache Framework design philosophy* explains a few of the design decisions of the framework.

### 3.11.1 Setting up the cache

The cache system requires a small amount of setup. Namely, you have to tell it where your cached data should live – whether in a database, on the filesystem or directly in memory. This is an important decision that affects your cache’s performance; yes, some cache types are faster than others.

Your cache preference goes in the `CACHES` setting in your settings file. Here’s an explanation of all available values for `CACHES`.

#### Memcached

The fastest, most efficient type of cache supported natively by Django, `Memcached` is an entirely memory-based cache server, originally developed to handle high loads at LiveJournal.com and subsequently open-sourced by Danga Interactive. It is used by sites such as Facebook and Wikipedia to reduce database access and dramatically increase site performance.

Memcached runs as a daemon and is allotted a specified amount of RAM. All it does is provide a fast interface for adding, retrieving and deleting data in the cache. All data is stored directly in memory, so there’s no overhead of database or filesystem usage.

After installing Memcached itself, you’ll need to install a Memcached binding. There are several Python Memcached bindings available; the two most common are `python-memcached` and `pylibmc`.

To use Memcached with Django:

- Set `BACKEND` to `django.core.cache.backends.memcached.MemcachedCache` or `django.core.cache.backends.memcached.PyLibMCCache` (depending on your chosen memcached binding)
- Set `LOCATION` to `ip:port` values, where `ip` is the IP address of the Memcached daemon and `port` is the port on which Memcached is running, or to a `unix:path` value, where `path` is the path to a Memcached Unix socket file.

In this example, Memcached is running on localhost (127.0.0.1) port 11211, using the `python-memcached` binding:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.memcached.MemcachedCache',
        'LOCATION': '127.0.0.1:11211',
    }
}
```

In this example, Memcached is available through a local Unix socket file `/tmp/memcached.sock` using the `python-memcached` binding:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.memcached.MemcachedCache',
        'LOCATION': 'unix:/tmp/memcached.sock',
    }
}
```

When using the `pylibmc` binding, do not include the `unix:/` prefix:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.memcached.PyLibMCCache',
        'LOCATION': '/tmp/memcached.sock',
    }
}
```

```
}
}
```

One excellent feature of Memcached is its ability to share a cache over multiple servers. This means you can run Memcached daemons on multiple machines, and the program will treat the group of machines as a *single* cache, without the need to duplicate cache values on each machine. To take advantage of this feature, include all server addresses in `LOCATION`, either separated by semicolons or as a list.

In this example, the cache is shared over Memcached instances running on IP address 172.19.26.240 and 172.19.26.242, both on port 11211:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.memcached.MemcachedCache',
        'LOCATION': [
            '172.19.26.240:11211',
            '172.19.26.242:11211',
        ]
    }
}
```

In the following example, the cache is shared over Memcached instances running on the IP addresses 172.19.26.240 (port 11211), 172.19.26.242 (port 11212), and 172.19.26.244 (port 11213):

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.memcached.MemcachedCache',
        'LOCATION': [
            '172.19.26.240:11211',
            '172.19.26.242:11212',
            '172.19.26.244:11213',
        ]
    }
}
```

A final point about Memcached is that memory-based caching has a disadvantage: because the cached data is stored in memory, the data will be lost if your server crashes. Clearly, memory isn't intended for permanent data storage, so don't rely on memory-based caching as your only data storage. Without a doubt, *none* of the Django caching backends should be used for permanent storage – they're all intended to be solutions for caching, not storage – but we point this out here because memory-based caching is particularly temporary.

## Database caching

Django can store its cached data in your database. This works best if you've got a fast, well-indexed database server.

To use a database table as your cache backend:

- Set `BACKEND` to `django.core.cache.backends.db.DatabaseCache`
- Set `LOCATION` to `tablename`, the name of the database table. This name can be whatever you want, as long as it's a valid table name that's not already being used in your database.

In this example, the cache table's name is `my_cache_table`:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.db.DatabaseCache',
        'LOCATION': 'my_cache_table',
    }
}
```

```
}  
}
```

## Creating the cache table

Before using the database cache, you must create the cache table with this command:

```
python manage.py createcachetable
```

This creates a table in your database that is in the proper format that Django's database-cache system expects. The name of the table is taken from `LOCATION`.

If you are using multiple database caches, `createcachetable` creates one table for each cache.

If you are using multiple databases, `createcachetable` observes the `allow_migrate()` method of your database routers (see below).

Like `migrate`, `createcachetable` won't touch an existing table. It will only create missing tables.

To print the SQL that would be run, rather than run it, use the `createcachetable --dry-run` option.

## Multiple databases

If you use database caching with multiple databases, you'll also need to set up routing instructions for your database cache table. For the purposes of routing, the database cache table appears as a model named `CacheEntry`, in an application named `django_cache`. This model won't appear in the models cache, but the model details can be used for routing purposes.

For example, the following router would direct all cache read operations to `cache_replica`, and all write operations to `cache_primary`. The cache table will only be synchronized onto `cache_primary`:

```
class CacheRouter(object):  
    """A router to control all database cache operations"""  
  
    def db_for_read(self, model, **hints):  
        "All cache read operations go to the replica"  
        if model._meta.app_label == 'django_cache':  
            return 'cache_replica'  
        return None  
  
    def db_for_write(self, model, **hints):  
        "All cache write operations go to primary"  
        if model._meta.app_label == 'django_cache':  
            return 'cache_primary'  
        return None  
  
    def allow_migrate(self, db, app_label, model_name=None, **hints):  
        "Only install the cache model on primary"  
        if app_label == 'django_cache':  
            return db == 'cache_primary'  
        return None
```

If you don't specify routing directions for the database cache model, the cache backend will use the default database.

Of course, if you don't use the database cache backend, you don't need to worry about providing routing instructions for the database cache model.

## Filesystem caching

The file-based backend serializes and stores each cache value as a separate file. To use this backend set `BACKEND` to `"django.core.cache.backends.filebased.FileBasedCache"` and `LOCATION` to a suitable directory. For example, to store cached data in `/var/tmp/django_cache`, use this setting:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.filebased.FileBasedCache',
        'LOCATION': '/var/tmp/django_cache',
    }
}
```

If you're on Windows, put the drive letter at the beginning of the path, like this:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.filebased.FileBasedCache',
        'LOCATION': 'c:/foo/bar',
    }
}
```

The directory path should be absolute – that is, it should start at the root of your filesystem. It doesn't matter whether you put a slash at the end of the setting.

Make sure the directory pointed-to by this setting exists and is readable and writable by the system user under which your Web server runs. Continuing the above example, if your server runs as the user `apache`, make sure the directory `/var/tmp/django_cache` exists and is readable and writable by the user `apache`.

## Local-memory caching

This is the default cache if another is not specified in your settings file. If you want the speed advantages of in-memory caching but don't have the capability of running Memcached, consider the local-memory cache backend. This cache is per-process (see below) and thread-safe. To use it, set `BACKEND` to `"django.core.cache.backends.locmem.LocMemCache"`. For example:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.locmem.LocMemCache',
        'LOCATION': 'unique-snowflake',
    }
}
```

The cache `LOCATION` is used to identify individual memory stores. If you only have one `locmem` cache, you can omit the `LOCATION`; however, if you have more than one local memory cache, you will need to assign a name to at least one of them in order to keep them separate.

Note that each process will have its own private cache instance, which means no cross-process caching is possible. This obviously also means the local memory cache isn't particularly memory-efficient, so it's probably not a good choice for production environments. It's nice for development.

## Dummy caching (for development)

Finally, Django comes with a “dummy” cache that doesn’t actually cache – it just implements the cache interface without doing anything.

This is useful if you have a production site that uses heavy-duty caching in various places but a development/test environment where you don’t want to cache and don’t want to have to change your code to special-case the latter. To activate dummy caching, set `BACKEND` like so:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.dummy.DummyCache',
    }
}
```

## Using a custom cache backend

While Django includes support for a number of cache backends out-of-the-box, sometimes you might want to use a customized cache backend. To use an external cache backend with Django, use the Python import path as the `BACKEND` of the `CACHES` setting, like so:

```
CACHES = {
    'default': {
        'BACKEND': 'path.to.backend',
    }
}
```

If you’re building your own backend, you can use the standard cache backends as reference implementations. You’ll find the code in the `django/core/cache/backends/` directory of the Django source.

Note: Without a really compelling reason, such as a host that doesn’t support them, you should stick to the cache backends included with Django. They’ve been well-tested and are easy to use.

## Cache arguments

Each cache backend can be given additional arguments to control caching behavior. These arguments are provided as additional keys in the `CACHES` setting. Valid arguments are as follows:

- `TIMEOUT`: The default timeout, in seconds, to use for the cache. This argument defaults to 300 seconds (5 minutes). You can set `TIMEOUT` to `None` so that, by default, cache keys never expire. A value of 0 causes keys to immediately expire (effectively “don’t cache”).
- `OPTIONS`: Any options that should be passed to the cache backend. The list of valid options will vary with each backend, and cache backends backed by a third-party library will pass their options directly to the underlying cache library.

Cache backends that implement their own culling strategy (i.e., the `locmem`, `filesystem` and `database` backends) will honor the following options:

- `MAX_ENTRIES`: The maximum number of entries allowed in the cache before old values are deleted. This argument defaults to 300.
- `CULL_FREQUENCY`: The fraction of entries that are culled when `MAX_ENTRIES` is reached. The actual ratio is  $1 / \text{CULL\_FREQUENCY}$ , so set `CULL_FREQUENCY` to 2 to cull half the entries when `MAX_ENTRIES` is reached. This argument should be an integer and defaults to 3.

A value of 0 for `CULL_FREQUENCY` means that the entire cache will be dumped when `MAX_ENTRIES` is reached. On some backends (database in particular) this makes culling *much* faster at the expense of more cache misses.

- `KEY_PREFIX`: A string that will be automatically included (prepended by default) to all cache keys used by the Django server.

See the [cache documentation](#) for more information.

- `VERSION`: The default version number for cache keys generated by the Django server.

See the [cache documentation](#) for more information.

- `KEY_FUNCTION`: A string containing a dotted path to a function that defines how to compose a prefix, version and key into a final cache key.

See the [cache documentation](#) for more information.

In this example, a filesystem backend is being configured with a timeout of 60 seconds, and a maximum capacity of 1000 items:

```
CACHES = {
    'default': {
        'BACKEND': 'django.core.cache.backends.filebased.FileBasedCache',
        'LOCATION': '/var/tmp/django_cache',
        'TIMEOUT': 60,
        'OPTIONS': {
            'MAX_ENTRIES': 1000
        }
    }
}
```

Invalid arguments are silently ignored, as are invalid values of known arguments.

### 3.11.2 The per-site cache

Once the cache is set up, the simplest way to use caching is to cache your entire site. You'll need to add `'django.middleware.cache.UpdateCacheMiddleware'` and `'django.middleware.cache.FetchFromCacheMiddleware'` to your `MIDDLEWARE` setting, as in this example:

```
MIDDLEWARE = [
    'django.middleware.cache.UpdateCacheMiddleware',
    'django.middleware.common.CommonMiddleware',
    'django.middleware.cache.FetchFromCacheMiddleware',
]
```

**Note:** No, that's not a typo: the “update” middleware must be first in the list, and the “fetch” middleware must be last. The details are a bit obscure, but see [Order of MIDDLEWARE](#) below if you'd like the full story.

Then, add the following required settings to your Django settings file:

- `CACHE_MIDDLEWARE_ALIAS` – The cache alias to use for storage.
- `CACHE_MIDDLEWARE_SECONDS` – The number of seconds each page should be cached.
- `CACHE_MIDDLEWARE_KEY_PREFIX` – If the cache is shared across multiple sites using the same Django installation, set this to the name of the site, or some other string that is unique to this Django instance, to prevent key collisions. Use an empty string if you don't care.

`FetchFromCacheMiddleware` caches GET and HEAD responses with status 200, where the request and response headers allow. Responses to requests for the same URL with different query parameters are considered to be unique pages and are cached separately. This middleware expects that a HEAD request is answered with the same response headers as the corresponding GET request; in which case it can return a cached GET response for HEAD request.

Additionally, `UpdateCacheMiddleware` automatically sets a few headers in each `HttpResponse`:

- Sets the `Last-Modified` header to the current date/time when a fresh (not cached) version of the page is requested.
- Sets the `Expires` header to the current date/time plus the defined `CACHE_MIDDLEWARE_SECONDS`.
- Sets the `Cache-Control` header to give a max age for the page – again, from the `CACHE_MIDDLEWARE_SECONDS` setting.

See [Middleware](#) for more on middleware.

If a view sets its own cache expiry time (i.e. it has a max-age section in its `Cache-Control` header) then the page will be cached until the expiry time, rather than `CACHE_MIDDLEWARE_SECONDS`. Using the decorators in `django.views.decorators.cache` you can easily set a view's expiry time (using the `cache_control()` decorator) or disable caching for a view (using the `never_cache()` decorator). See the [using other headers](#) section for more on these decorators. If `USE_I18N` is set to `True` then the generated cache key will include the name of the active *language* – see also [How Django discovers language preference](#)). This allows you to easily cache multilingual sites without having to create the cache key yourself.

Cache keys also include the active *language* when `USE_L10N` is set to `True` and the *current time zone* when `USE_TZ` is set to `True`.

### 3.11.3 The per-view cache

`django.views.decorators.cache.cache_page()`

A more granular way to use the caching framework is by caching the output of individual views. `django.views.decorators.cache` defines a `cache_page` decorator that will automatically cache the view's response for you. It's easy to use:

```
from django.views.decorators.cache import cache_page

@cache_page(60 * 15)
def my_view(request):
    ...
```

`cache_page` takes a single argument: the cache timeout, in seconds. In the above example, the result of the `my_view()` view will be cached for 15 minutes. (Note that we've written it as `60 * 15` for the purpose of readability. `60 * 15` will be evaluated to `900` – that is, 15 minutes multiplied by 60 seconds per minute.)

The per-view cache, like the per-site cache, is keyed off of the URL. If multiple URLs point at the same view, each URL will be cached separately. Continuing the `my_view` example, if your `URLconf` looks like this:

```
urlpatterns = [
    url(r'^foo/([0-9]{1,2})/$', my_view),
]
```

then requests to `/foo/1/` and `/foo/23/` will be cached separately, as you may expect. But once a particular URL (e.g., `/foo/23/`) has been requested, subsequent requests to that URL will use the cache.

`cache_page` can also take an optional keyword argument, `cache`, which directs the decorator to use a specific cache (from your `CACHES` setting) when caching view results. By default, the `default` cache will be used, but you can specify any cache you want:

```
@cache_page(60 * 15, cache="special_cache")
def my_view(request):
    ...
```

You can also override the cache prefix on a per-view basis. `cache_page` takes an optional keyword argument, `key_prefix`, which works in the same way as the `CACHE_MIDDLEWARE_KEY_PREFIX` setting for the middleware. It can be used like this:

```
@cache_page(60 * 15, key_prefix="site1")
def my_view(request):
    ...
```

The `key_prefix` and `cache` arguments may be specified together. The `key_prefix` argument and the `KEY_PREFIX` specified under `CACHES` will be concatenated.

### Specifying per-view cache in the URLconf

The examples in the previous section have hard-coded the fact that the view is cached, because `cache_page` alters the `my_view` function in place. This approach couples your view to the cache system, which is not ideal for several reasons. For instance, you might want to reuse the view functions on another, cache-less site, or you might want to distribute the views to people who might want to use them without being cached. The solution to these problems is to specify the per-view cache in the URLconf rather than next to the view functions themselves.

Doing so is easy: simply wrap the view function with `cache_page` when you refer to it in the URLconf. Here's the old URLconf from earlier:

```
urlpatterns = [
    url(r'^foo/([0-9]{1,2})/$', my_view),
]
```

Here's the same thing, with `my_view` wrapped in `cache_page`:

```
from django.views.decorators.cache import cache_page

urlpatterns = [
    url(r'^foo/([0-9]{1,2})/$', cache_page(60 * 15)(my_view)),
]
```

### 3.11.4 Template fragment caching

If you're after even more control, you can also cache template fragments using the `cache` template tag. To give your template access to this tag, put `{% load cache %}` near the top of your template.

The `{% cache %}` template tag caches the contents of the block for a given amount of time. It takes at least two arguments: the cache timeout, in seconds, and the name to give the cache fragment. The name will be taken as is, do not use a variable. For example:

```
{% load cache %}
{% cache 500 sidebar %}
    .. sidebar ..
{% endcache %}
```

Sometimes you might want to cache multiple copies of a fragment depending on some dynamic data that appears inside the fragment. For example, you might want a separate cached copy of the sidebar used in the previous example

for every user of your site. Do this by passing additional arguments to the `{% cache %}` template tag to uniquely identify the cache fragment:

```
{% load cache %}
{% cache 500 sidebar request.user.username %}
    .. sidebar for logged in user ..
{% endcache %}
```

It's perfectly fine to specify more than one argument to identify the fragment. Simply pass as many arguments to `{% cache %}` as you need.

If `USE_I18N` is set to `True` the per-site middleware cache will *respect the active language*. For the `cache` template tag you could use one of the *translation-specific variables* available in templates to achieve the same result:

```
{% load i18n %}
{% load cache %}

{% get_current_language as LANGUAGE_CODE %}

{% cache 600 welcome LANGUAGE_CODE %}
    {% trans "Welcome to example.com" %}
{% endcache %}
```

The cache timeout can be a template variable, as long as the template variable resolves to an integer value. For example, if the template variable `my_timeout` is set to the value `600`, then the following two examples are equivalent:

```
{% cache 600 sidebar %} ... {% endcache %}
{% cache my_timeout sidebar %} ... {% endcache %}
```

This feature is useful in avoiding repetition in templates. You can set the timeout in a variable, in one place, and just reuse that value.

By default, the cache tag will try to use the cache called “`template_fragments`”. If no such cache exists, it will fall back to using the default cache. You may select an alternate cache backend to use with the `using` keyword argument, which must be the last argument to the tag.

```
{% cache 300 local-thing ... using="localcache" %}
```

It is considered an error to specify a cache name that is not configured.

`django.core.cache.utils.make_template_fragment_key` (*fragment\_name*, *vary\_on=None*)

If you want to obtain the cache key used for a cached fragment, you can use `make_template_fragment_key`. `fragment_name` is the same as second argument to the `cache` template tag; `vary_on` is a list of all additional arguments passed to the tag. This function can be useful for invalidating or overwriting a cached item, for example:

```
>>> from django.core.cache import cache
>>> from django.core.cache.utils import make_template_fragment_key
# cache key for {% cache 500 sidebar username %}
>>> key = make_template_fragment_key('sidebar', [username])
>>> cache.delete(key) # invalidates cached template fragment
```

### 3.11.5 The low-level cache API

Sometimes, caching an entire rendered page doesn't gain you very much and is, in fact, inconvenient overkill.

Perhaps, for instance, your site includes a view whose results depend on several expensive queries, the results of which change at different intervals. In this case, it would not be ideal to use the full-page caching that the per-site or per-view

cache strategies offer, because you wouldn't want to cache the entire result (since some of the data changes often), but you'd still want to cache the results that rarely change.

For cases like this, Django exposes a simple, low-level cache API. You can use this API to store objects in the cache with any level of granularity you like. You can cache any Python object that can be pickled safely: strings, dictionaries, lists of model objects, and so forth. (Most common Python objects can be pickled; refer to the Python documentation for more information about pickling.)

## Accessing the cache

`django.core.cache.caches`

You can access the caches configured in the `CACHES` setting through a dict-like object: `django.core.cache.caches`. Repeated requests for the same alias in the same thread will return the same object.

```
>>> from django.core.cache import caches
>>> cache1 = caches['myalias']
>>> cache2 = caches['myalias']
>>> cache1 is cache2
True
```

If the named key does not exist, `InvalidCacheBackendError` will be raised.

To provide thread-safety, a different instance of the cache backend will be returned for each thread.

`django.core.cache.cache`

As a shortcut, the default cache is available as `django.core.cache.cache`:

```
>>> from django.core.cache import cache
```

This object is equivalent to `caches['default']`.

## Basic usage

The basic interface is `set(key, value, timeout)` and `get(key)`:

```
>>> cache.set('my_key', 'hello, world!', 30)
>>> cache.get('my_key')
'hello, world!'
```

`key` should be a `str` (or `unicode` on Python 2), and `value` can be any picklable Python object.

The `timeout` argument is optional and defaults to the `timeout` argument of the appropriate backend in the `CACHES` setting (explained above). It's the number of seconds the value should be stored in the cache. Passing in `None` for `timeout` will cache the value forever. A `timeout` of 0 won't cache the value.

If the object doesn't exist in the cache, `cache.get()` returns `None`:

```
>>> # Wait 30 seconds for 'my_key' to expire...
>>> cache.get('my_key')
None
```

We advise against storing the literal value `None` in the cache, because you won't be able to distinguish between your stored `None` value and a cache miss signified by a return value of `None`.

`cache.get()` can take a `default` argument. This specifies which value to return if the object doesn't exist in the cache:

```
>>> cache.get('my_key', 'has expired')
'has expired'
```

To add a key only if it doesn't already exist, use the `add()` method. It takes the same parameters as `set()`, but it will not attempt to update the cache if the key specified is already present:

```
>>> cache.set('add_key', 'Initial value')
>>> cache.add('add_key', 'New value')
>>> cache.get('add_key')
'Initial value'
```

If you need to know whether `add()` stored a value in the cache, you can check the return value. It will return `True` if the value was stored, `False` otherwise.

If you want to get a key's value or set a value if the key isn't in the cache, there is the `get_or_set()` method. It takes the same parameters as `get()` but the default is set as the new cache value for that key, rather than simply returned:

```
>>> cache.get('my_new_key') # returns None
>>> cache.get_or_set('my_new_key', 'my new value', 100)
'my new value'
```

You can also pass any callable as a *default* value:

```
>>> import datetime
>>> cache.get_or_set('some-timestamp-key', datetime.datetime.now)
datetime.datetime(2014, 12, 11, 0, 15, 49, 457920)
```

The `get_or_set()` method was added.

There's also a `get_many()` interface that only hits the cache once. `get_many()` returns a dictionary with all the keys you asked for that actually exist in the cache (and haven't expired):

```
>>> cache.set('a', 1)
>>> cache.set('b', 2)
>>> cache.set('c', 3)
>>> cache.get_many(['a', 'b', 'c'])
{'a': 1, 'b': 2, 'c': 3}
```

To set multiple values more efficiently, use `set_many()` to pass a dictionary of key-value pairs:

```
>>> cache.set_many({'a': 1, 'b': 2, 'c': 3})
>>> cache.get_many(['a', 'b', 'c'])
{'a': 1, 'b': 2, 'c': 3}
```

Like `cache.set()`, `set_many()` takes an optional `timeout` parameter.

You can delete keys explicitly with `delete()`. This is an easy way of clearing the cache for a particular object:

```
>>> cache.delete('a')
```

If you want to clear a bunch of keys at once, `delete_many()` can take a list of keys to be cleared:

```
>>> cache.delete_many(['a', 'b', 'c'])
```

Finally, if you want to delete all the keys in the cache, use `cache.clear()`. Be careful with this; `clear()` will remove *everything* from the cache, not just the keys set by your application.

```
>>> cache.clear()
```

You can also increment or decrement a key that already exists using the `incr()` or `decr()` methods, respectively. By default, the existing cache value will be incremented or decremented by 1. Other increment/decrement values can be specified by providing an argument to the increment/decrement call. A `ValueError` will be raised if you attempt to increment or decrement a nonexistent cache key.:

```
>>> cache.set('num', 1)
>>> cache.incr('num')
2
>>> cache.incr('num', 10)
12
>>> cache.decr('num')
11
>>> cache.decr('num', 5)
6
```

---

**Note:** `incr()/decr()` methods are not guaranteed to be atomic. On those backends that support atomic increment/decrement (most notably, the memcached backend), increment and decrement operations will be atomic. However, if the backend doesn't natively provide an increment/decrement operation, it will be implemented using a two-step retrieve/update.

---

You can close the connection to your cache with `close()` if implemented by the cache backend.

```
>>> cache.close()
```

---

**Note:** For caches that don't implement `close` methods it is a no-op.

---

### Cache key prefixing

If you are sharing a cache instance between servers, or between your production and development environments, it's possible for data cached by one server to be used by another server. If the format of cached data is different between servers, this can lead to some very hard to diagnose problems.

To prevent this, Django provides the ability to prefix all cache keys used by a server. When a particular cache key is saved or retrieved, Django will automatically prefix the cache key with the value of the `KEY_PREFIX` cache setting.

By ensuring each Django instance has a different `KEY_PREFIX`, you can ensure that there will be no collisions in cache values.

### Cache versioning

When you change running code that uses cached values, you may need to purge any existing cached values. The easiest way to do this is to flush the entire cache, but this can lead to the loss of cache values that are still valid and useful.

Django provides a better way to target individual cache values. Django's cache framework has a system-wide version identifier, specified using the `VERSION` cache setting. The value of this setting is automatically combined with the cache prefix and the user-provided cache key to obtain the final cache key.

By default, any key request will automatically include the site default cache key version. However, the primitive cache functions all include a `version` argument, so you can specify a particular cache key version to set or get. For example:

```
>>> # Set version 2 of a cache key
>>> cache.set('my_key', 'hello world!', version=2)
>>> # Get the default version (assuming version=1)
>>> cache.get('my_key')
None
>>> # Get version 2 of the same key
>>> cache.get('my_key', version=2)
'hello world!'
```

The version of a specific key can be incremented and decremented using the `incr_version()` and `decr_version()` methods. This enables specific keys to be bumped to a new version, leaving other keys unaffected. Continuing our previous example:

```
>>> # Increment the version of 'my_key'
>>> cache.incr_version('my_key')
>>> # The default version still isn't available
>>> cache.get('my_key')
None
# Version 2 isn't available, either
>>> cache.get('my_key', version=2)
None
>>> # But version 3 is available
>>> cache.get('my_key', version=3)
'hello world!'
```

## Cache key transformation

As described in the previous two sections, the cache key provided by a user is not used verbatim – it is combined with the cache prefix and key version to provide a final cache key. By default, the three parts are joined using colons to produce a final string:

```
def make_key(key, key_prefix, version):
    return ':'.join([key_prefix, str(version), key])
```

If you want to combine the parts in different ways, or apply other processing to the final key (e.g., taking a hash digest of the key parts), you can provide a custom key function.

The `KEY_FUNCTION` cache setting specifies a dotted-path to a function matching the prototype of `make_key()` above. If provided, this custom key function will be used instead of the default key combining function.

## Cache key warnings

Memcached, the most commonly-used production cache backend, does not allow cache keys longer than 250 characters or containing whitespace or control characters, and using such keys will cause an exception. To encourage cache-portable code and minimize unpleasant surprises, the other built-in cache backends issue a warning (`django.core.cache.backends.base.CacheKeyWarning`) if a key is used that would cause an error on memcached.

If you are using a production backend that can accept a wider range of keys (a custom backend, or one of the non-memcached built-in backends), and want to use this wider range without warnings, you can silence `CacheKeyWarning` with this code in the management module of one of your `INSTALLED_APPS`:

```
import warnings

from django.core.cache import CacheKeyWarning

warnings.simplefilter("ignore", CacheKeyWarning)
```

If you want to instead provide custom key validation logic for one of the built-in backends, you can subclass it, override just the `validate_key` method, and follow the instructions for *using a custom cache backend*. For instance, to do this for the `locmem` backend, put this code in a module:

```
from django.core.cache.backends.locmem import LocMemCache

class CustomLocMemCache(LocMemCache):
    def validate_key(self, key):
        """Custom validation, raising exceptions or warnings as needed."""
        ...
```

...and use the dotted Python path to this class in the `BACKEND` portion of your `CACHES` setting.

### 3.11.6 Downstream caches

So far, this document has focused on caching your *own* data. But another type of caching is relevant to Web development, too: caching performed by “downstream” caches. These are systems that cache pages for users even before the request reaches your website.

Here are a few examples of downstream caches:

- Your ISP may cache certain pages, so if you requested a page from <https://example.com/>, your ISP would send you the page without having to access `example.com` directly. The maintainers of `example.com` have no knowledge of this caching; the ISP sits between `example.com` and your Web browser, handling all of the caching transparently.
- Your Django website may sit behind a *proxy cache*, such as Squid Web Proxy Cache (<http://www.squid-cache.org/>), that caches pages for performance. In this case, each request first would be handled by the proxy, and it would be passed to your application only if needed.
- Your Web browser caches pages, too. If a Web page sends out the appropriate headers, your browser will use the local cached copy for subsequent requests to that page, without even contacting the Web page again to see whether it has changed.

Downstream caching is a nice efficiency boost, but there’s a danger to it: Many Web pages’ contents differ based on authentication and a host of other variables, and cache systems that blindly save pages based purely on URLs could expose incorrect or sensitive data to subsequent visitors to those pages.

For example, say you operate a Web email system, and the contents of the “inbox” page obviously depend on which user is logged in. If an ISP blindly cached your site, then the first user who logged in through that ISP would have their user-specific inbox page cached for subsequent visitors to the site. That’s not cool.

Fortunately, HTTP provides a solution to this problem. A number of HTTP headers exist to instruct downstream caches to differ their cache contents depending on designated variables, and to tell caching mechanisms not to cache particular pages. We’ll look at some of these headers in the sections that follow.

### 3.11.7 Using vary headers

The `Vary` header defines which request headers a cache mechanism should take into account when building its cache key. For example, if the contents of a Web page depend on a user’s language preference, the page is said to “vary on

language.”

By default, Django’s cache system creates its cache keys using the requested fully-qualified URL – e.g., “https://www.example.com/stories/2005/?order\_by=author”. This means every request to that URL will use the same cached version, regardless of user-agent differences such as cookies or language preferences. However, if this page produces different content based on some difference in request headers – such as a cookie, or a language, or a user-agent – you’ll need to use the Vary header to tell caching mechanisms that the page output depends on those things.

To do this in Django, use the convenient `django.views.decorators.vary.vary_on_headers()` view decorator, like so:

```
from django.views.decorators.vary import vary_on_headers

@vary_on_headers('User-Agent')
def my_view(request):
    ...
```

In this case, a caching mechanism (such as Django’s own cache middleware) will cache a separate version of the page for each unique user-agent.

The advantage to using the `vary_on_headers` decorator rather than manually setting the Vary header (using something like `response['Vary'] = 'user-agent'`) is that the decorator *adds* to the Vary header (which may already exist), rather than setting it from scratch and potentially overriding anything that was already in there.

You can pass multiple headers to `vary_on_headers()`:

```
@vary_on_headers('User-Agent', 'Cookie')
def my_view(request):
    ...
```

This tells downstream caches to vary on *both*, which means each combination of user-agent and cookie will get its own cache value. For example, a request with the user-agent Mozilla and the cookie value `foo=bar` will be considered different from a request with the user-agent Mozilla and the cookie value `foo=ham`.

Because varying on cookie is so common, there’s a `django.views.decorators.vary.vary_on_cookie()` decorator. These two views are equivalent:

```
@vary_on_cookie
def my_view(request):
    ...

@vary_on_headers('Cookie')
def my_view(request):
    ...
```

The headers you pass to `vary_on_headers` are not case sensitive; “User-Agent” is the same thing as “user-agent”.

You can also use a helper function, `django.utils.cache.patch_vary_headers()`, directly. This function sets, or adds to, the Vary header. For example:

```
from django.shortcuts import render
from django.utils.cache import patch_vary_headers

def my_view(request):
    ...
    response = render(request, 'template_name', context)
    patch_vary_headers(response, ['Cookie'])
    return response
```

`patch_vary_headers` takes an `HttpResponse` instance as its first argument and a list/tuple of case-insensitive header names as its second argument.

For more on Vary headers, see the [official Vary spec](#).

### 3.11.8 Controlling cache: Using other headers

Other problems with caching are the privacy of data and the question of where data should be stored in a cascade of caches.

A user usually faces two kinds of caches: their own browser cache (a private cache) and their provider’s cache (a public cache). A public cache is used by multiple users and controlled by someone else. This poses problems with sensitive data—you don’t want, say, your bank account number stored in a public cache. So Web applications need a way to tell caches which data is private and which is public.

The solution is to indicate a page’s cache should be “private.” To do this in Django, use the `cache_control()` view decorator. Example:

```
from django.views.decorators.cache import cache_control

@cache_control(private=True)
def my_view(request):
    ...
```

This decorator takes care of sending out the appropriate HTTP header behind the scenes.

Note that the cache control settings “private” and “public” are mutually exclusive. The decorator ensures that the “public” directive is removed if “private” should be set (and vice versa). An example use of the two directives would be a blog site that offers both private and public entries. Public entries may be cached on any shared cache. The following code uses `patch_cache_control()`, the manual way to modify the cache control header (it is internally called by the `cache_control()` decorator):

```
from django.views.decorators.cache import patch_cache_control
from django.views.decorators.vary import vary_on_cookie

@vary_on_cookie
def list_blog_entries_view(request):
    if request.user.is_anonymous:
        response = render_only_public_entries()
        patch_cache_control(response, public=True)
    else:
        response = render_private_and_public_entries(request.user)
        patch_cache_control(response, private=True)

    return response
```

You can control downstream caches in other ways as well (see [RFC 7234](#) for details on HTTP caching). For example, even if you don’t use Django’s server-side cache framework, you can still tell clients to cache a view for a certain amount of time with the `max-age` directive:

```
from django.views.decorators.cache import cache_control

@cache_control(max_age=3600)
def my_view(request):
    ...
```

(If you *do* use the caching middleware, it already sets the `max-age` with the value of the `CACHE_MIDDLEWARE_SECONDS` setting. In that case, the custom `max_age` from the `cache_control()` decorator will take precedence, and the header values will be merged correctly.)

Any valid `Cache-Control` response directive is valid in `cache_control()`. Here are some more examples:

- `no_transform=True`
- `must_revalidate=True`
- `stale_while_revalidate=num_seconds`

The full list of known directives can be found in the [IANA registry](#) (note that not all of them apply to responses).

If you want to use headers to disable caching altogether, `never_cache()` is a view decorator that adds headers to ensure the response won't be cached by browsers or other caches. Example:

```
from django.views.decorators.cache import never_cache

@never_cache
def myview(request):
    ...
```

### 3.11.9 Order of MIDDLEWARE

If you use caching middleware, it's important to put each half in the right place within the `MIDDLEWARE` setting. That's because the cache middleware needs to know which headers by which to vary the cache storage. Middleware always adds something to the `Vary` response header when it can.

`UpdateCacheMiddleware` runs during the response phase, where middleware is run in reverse order, so an item at the top of the list runs *last* during the response phase. Thus, you need to make sure that `UpdateCacheMiddleware` appears *before* any other middleware that might add something to the `Vary` header. The following middleware modules do so:

- `SessionMiddleware` adds `Cookie`
- `GZipMiddleware` adds `Accept-Encoding`
- `LocaleMiddleware` adds `Accept-Language`

`FetchFromCacheMiddleware`, on the other hand, runs during the request phase, where middleware is applied first-to-last, so an item at the top of the list runs *first* during the request phase. The `FetchFromCacheMiddleware` also needs to run after other middleware updates the `Vary` header, so `FetchFromCacheMiddleware` must be *after* any item that does so.

## 3.12 Conditional View Processing

HTTP clients can send a number of headers to tell the server about copies of a resource that they have already seen. This is commonly used when retrieving a Web page (using an HTTP `GET` request) to avoid sending all the data for something the client has already retrieved. However, the same headers can be used for all HTTP methods (`POST`, `PUT`, `DELETE`, etc.).

For each page (response) that Django sends back from a view, it might provide two HTTP headers: the `ETag` header and the `Last-Modified` header. These headers are optional on HTTP responses. They can be set by your view function, or you can rely on the `CommonMiddleware` middleware to set the `ETag` header.

When the client next requests the same resource, it might send along a header such as either `If-modified-since` or `If-unmodified-since`, containing the date of the last modification time it was sent, or either `If-match` or `If-none-match`,

containing the last ETag it was sent. If the current version of the page matches the ETag sent by the client, or if the resource has not been modified, a 304 status code can be sent back, instead of a full response, telling the client that nothing has changed. Depending on the header, if the page has been modified or does not match the ETag sent by the client, a 412 status code (Precondition Failed) may be returned.

When you need more fine-grained control you may use per-view conditional processing functions.

### 3.12.1 The condition decorator

Sometimes (in fact, quite often) you can create functions to rapidly compute the ETag value or the last-modified time for a resource, **without** needing to do all the computations needed to construct the full view. Django can then use these functions to provide an “early bailout” option for the view processing. Telling the client that the content has not been modified since the last request, perhaps.

These two functions are passed as parameters to the `django.views.decorators.http.condition` decorator. This decorator uses the two functions (you only need to supply one, if you can’t compute both quantities easily and quickly) to work out if the headers in the HTTP request match those on the resource. If they don’t match, a new copy of the resource must be computed and your normal view is called.

The `condition` decorator’s signature looks like this:

```
condition(etag_func=None, last_modified_func=None)
```

The two functions, to compute the ETag and the last modified time, will be passed the incoming `request` object and the same parameters, in the same order, as the view function they are helping to wrap. The function passed `last_modified_func` should return a standard datetime value specifying the last time the resource was modified, or `None` if the resource doesn’t exist. The function passed to the `etag` decorator should return a string representing the ETag for the resource, or `None` if it doesn’t exist.

Using this feature usefully is probably best explained with an example. Suppose you have this pair of models, representing a simple blog system:

```
import datetime
from django.db import models

class Blog(models.Model):
    ...

class Entry(models.Model):
    blog = models.ForeignKey(Blog)
    published = models.DateTimeField(default=datetime.datetime.now)
    ...
```

If the front page, displaying the latest blog entries, only changes when you add a new blog entry, you can compute the last modified time very quickly. You need the latest published date for every entry associated with that blog. One way to do this would be:

```
def latest_entry(request, blog_id):
    return Entry.objects.filter(blog=blog_id).latest("published").published
```

You can then use this function to provide early detection of an unchanged page for your front page view:

```
from django.views.decorators.http import condition

@condition(last_modified_func=latest_entry)
def front_page(request, blog_id):
    ...
```

### Be careful with the order of decorators

When `condition()` returns a conditional response, any decorators below it will be skipped and won't apply to the response. Therefore, any decorators that need to apply to both the regular view response and a conditional response must be above `condition()`. In particular, `vary_on_cookie()`, `vary_on_headers()`, and `cache_control()` should come first because [RFC 7232](#) requires that the headers they set be present on 304 responses.

---

## 3.12.2 Shortcuts for only computing one value

As a general rule, if you can provide functions to compute *both* the ETag and the last modified time, you should do so. You don't know which headers any given HTTP client will send you, so be prepared to handle both. However, sometimes only one value is easy to compute and Django provides decorators that handle only ETag or only last-modified computations.

The `django.views.decorators.http.etag` and `django.views.decorators.http.last_modified` decorators are passed the same type of functions as the `condition` decorator. Their signatures are:

```
etag(etag_func)
last_modified(last_modified_func)
```

We could write the earlier example, which only uses a last-modified function, using one of these decorators:

```
@last_modified(latest_entry)
def front_page(request, blog_id):
    ...
```

...or:

```
def front_page(request, blog_id):
    ...
    front_page = last_modified(latest_entry)(front_page)
```

### Use `condition` when testing both conditions

It might look nicer to some people to try and chain the `etag` and `last_modified` decorators if you want to test both preconditions. However, this would lead to incorrect behavior.

```
# Bad code. Don't do this!
@etag(etag_func)
@last_modified(last_modified_func)
def my_view(request):
    # ...

# End of bad code.
```

The first decorator doesn't know anything about the second and might answer that the response is not modified even if the second decorators would determine otherwise. The `condition` decorator uses both callback functions simultaneously to work out the right action to take.

### 3.12.3 Using the decorators with other HTTP methods

The `condition` decorator is useful for more than only GET and HEAD requests (HEAD requests are the same as GET in this situation). It can also be used to provide checking for POST, PUT and DELETE requests. In these situations, the idea isn't to return a "not modified" response, but to tell the client that the resource they are trying to change has been altered in the meantime.

For example, consider the following exchange between the client and server:

1. Client requests `/foo/`.
2. Server responds with some content with an ETag of `"abcd1234"`.
3. Client sends an HTTP PUT request to `/foo/` to update the resource. It also sends an `If-Match: "abcd1234"` header to specify the version it is trying to update.
4. Server checks to see if the resource has changed, by computing the ETag the same way it does for a GET request (using the same function). If the resource *has* changed, it will return a 412 status code, meaning "precondition failed".
5. Client sends a GET request to `/foo/`, after receiving a 412 response, to retrieve an updated version of the content before updating it.

The important thing this example shows is that the same functions can be used to compute the ETag and last modification values in all situations. In fact, you **should** use the same functions, so that the same values are returned every time.

### 3.12.4 Comparison with middleware conditional processing

You may notice that Django already provides simple and straightforward conditional GET handling via the `django.middleware.http.ConditionalGetMiddleware` and `CommonMiddleware`. While certainly being easy to use and suitable for many situations, those pieces of middleware functionality have limitations for advanced usage:

- They are applied globally to all views in your project
- They don't save you from generating the response itself, which may be expensive
- They are only appropriate for HTTP GET requests.

You should choose the most appropriate tool for your particular problem here. If you have a way to compute ETags and modification times quickly and if some view takes a while to generate the content, you should consider using the `condition` decorator described in this document. If everything already runs fairly quickly, stick to using the middleware and the amount of network traffic sent back to the clients will still be reduced if the view hasn't changed.

## 3.13 Cryptographic signing

The golden rule of Web application security is to never trust data from untrusted sources. Sometimes it can be useful to pass data through an untrusted medium. Cryptographically signed values can be passed through an untrusted channel safe in the knowledge that any tampering will be detected.

Django provides both a low-level API for signing values and a high-level API for setting and reading signed cookies, one of the most common uses of signing in Web applications.

You may also find signing useful for the following:

- Generating "recover my account" URLs for sending to users who have lost their password.
- Ensuring data stored in hidden form fields has not been tampered with.

- Generating one-time secret URLs for allowing temporary access to a protected resource, for example a downloadable file that a user has paid for.

### 3.13.1 Protecting the `SECRET_KEY`

When you create a new Django project using `startproject`, the `settings.py` file is generated automatically and gets a random `SECRET_KEY` value. This value is the key to securing signed data – it is vital you keep this secure, or attackers could use it to generate their own signed values.

### 3.13.2 Using the low-level API

Django’s signing methods live in the `django.core.signing` module. To sign a value, first instantiate a `Signer` instance:

```
>>> from django.core.signing import Signer
>>> signer = Signer()
>>> value = signer.sign('My string')
>>> value
'My string:GdMGD6HNQ_qdgxYP8yBZAdAIV1w'
```

The signature is appended to the end of the string, following the colon. You can retrieve the original value using the `unsign` method:

```
>>> original = signer.unsign(value)
>>> original
'My string'
```

If the signature or value have been altered in any way, a `django.core.signing.BadSignature` exception will be raised:

```
>>> from django.core import signing
>>> value += 'm'
>>> try:
...     original = signer.unsign(value)
... except signing.BadSignature:
...     print("Tampering detected!")
```

By default, the `Signer` class uses the `SECRET_KEY` setting to generate signatures. You can use a different secret by passing it to the `Signer` constructor:

```
>>> signer = Signer('my-other-secret')
>>> value = signer.sign('My string')
>>> value
'My string:EkfQJafvGyiofrdGnuthdxImIJw'
```

**class `Signer`** (*key=None, sep=':', salt=None*)

Returns a signer which uses `key` to generate signatures and `sep` to separate values. `sep` cannot be in the [URL safe base64 alphabet](#). This alphabet contains alphanumeric characters, hyphens, and underscores.

#### Using the `salt` argument

If you do not wish for every occurrence of a particular string to have the same signature hash, you can use the optional `salt` argument to the `Signer` class. Using a salt will seed the signing hash function with both the salt and your `SECRET_KEY`:

```
>>> signer = Signer()
>>> signer.sign('My string')
'My string:GdMGD6HNQ_qdgxYP8yBZAdAIV1w'
>>> signer = Signer(salt='extra')
>>> signer.sign('My string')
'My string:Ee7vGi-ING6n02gkcJ-QLHg6vFw'
>>> signer.unsign('My string:Ee7vGi-ING6n02gkcJ-QLHg6vFw')
'My string'
```

Using salt in this way puts the different signatures into different namespaces. A signature that comes from one namespace (a particular salt value) cannot be used to validate the same plaintext string in a different namespace that is using a different salt setting. The result is to prevent an attacker from using a signed string generated in one place in the code as input to another piece of code that is generating (and verifying) signatures using a different salt.

Unlike your `SECRET_KEY`, your salt argument does not need to stay secret.

### Verifying timestamped values

`TimestampSigner` is a subclass of `Signer` that appends a signed timestamp to the value. This allows you to confirm that a signed value was created within a specified period of time:

```
>>> from datetime import timedelta
>>> from django.core.signing import TimestampSigner
>>> signer = TimestampSigner()
>>> value = signer.sign('hello')
>>> value
'hello:1NMg5H:oPVuCqlJWmChm1rA2lyTutelC-c'
>>> signer.unsign(value)
'hello'
>>> signer.unsign(value, max_age=10)
...
SignatureExpired: Signature age 15.5289158821 > 10 seconds
>>> signer.unsign(value, max_age=20)
'hello'
>>> signer.unsign(value, max_age=timedelta(seconds=20))
'hello'
```

**class** `TimestampSigner` (*key=None, sep='.', salt=None*)

**sign** (*value*)

Sign value and append current timestamp to it.

**unsign** (*value, max\_age=None*)

Checks if value was signed less than `max_age` seconds ago, otherwise raises `SignatureExpired`. The `max_age` parameter can accept an integer or a `datetime.timedelta` object.

### Protecting complex data structures

If you wish to protect a list, tuple or dictionary you can do so using the signing module's `dumps` and `loads` functions. These imitate Python's `pickle` module, but use JSON serialization under the hood. JSON ensures that even if your `SECRET_KEY` is stolen an attacker will not be able to execute arbitrary commands by exploiting the pickle format:

```
>>> from django.core import signing
>>> value = signing.dumps({"foo": "bar"})
>>> value
```

```
'eyJmb28iOiJiYXIfQ:1NMg1b:zGcDE4-TCkaeGzLeW9UQwZesciI'  
>>> signing.loads(value)  
{'foo': 'bar'}
```

Because of the nature of JSON (there is no native distinction between lists and tuples) if you pass in a tuple, you will get a list from `signing.loads(object)`:

```
>>> from django.core import signing  
>>> value = signing.dumps(('a', 'b', 'c'))  
>>> signing.loads(value)  
['a', 'b', 'c']
```

**dumps** (*obj*, *key=None*, *salt='django.core.signing'*, *compress=False*)

Returns URL-safe, sha1 signed base64 compressed JSON string. Serialized object is signed using *TimestampSigner*.

**loads** (*string*, *key=None*, *salt='django.core.signing'*, *max\_age=None*)

Reverse of `dumps()`, raises `BadSignature` if signature fails. Checks `max_age` (in seconds) if given.

## 3.14 Sending email

Although Python makes sending email relatively easy via the `smtplib` module, Django provides a couple of light wrappers over it. These wrappers are provided to make sending email extra quick, to make it easy to test email sending during development, and to provide support for platforms that can't use SMTP.

The code lives in the `django.core.mail` module.

### 3.14.1 Quick example

In two lines:

```
from django.core.mail import send_mail  
  
send_mail(  
    'Subject here',  
    'Here is the message.',  
    'from@example.com',  
    ['to@example.com'],  
    fail_silently=False,  
)
```

Mail is sent using the SMTP host and port specified in the `EMAIL_HOST` and `EMAIL_PORT` settings. The `EMAIL_HOST_USER` and `EMAIL_HOST_PASSWORD` settings, if set, are used to authenticate to the SMTP server, and the `EMAIL_USE_TLS` and `EMAIL_USE_SSL` settings control whether a secure connection is used.

---

**Note:** The character set of email sent with `django.core.mail` will be set to the value of your `DEFAULT_CHARSET` setting.

---

### 3.14.2 `send_mail()`

**send\_mail** (*subject*, *message*, *from\_email*, *recipient\_list*, *fail\_silently=False*, *auth\_user=None*,  
*auth\_password=None*, *connection=None*, *html\_message=None*)

The simplest way to send email is using `django.core.mail.send_mail()`.

The `subject`, `message`, `from_email` and `recipient_list` parameters are required.

- `subject`: A string.
- `message`: A string.
- `from_email`: A string.
- `recipient_list`: A list of strings, each an email address. Each member of `recipient_list` will see the other recipients in the “To:” field of the email message.
- `fail_silently`: A boolean. If it’s `False`, `send_mail` will raise an `smtpplib.SMTPException`. See the `smtpplib` docs for a list of possible exceptions, all of which are subclasses of `SMTPException`.
- `auth_user`: The optional username to use to authenticate to the SMTP server. If this isn’t provided, Django will use the value of the `EMAIL_HOST_USER` setting.
- `auth_password`: The optional password to use to authenticate to the SMTP server. If this isn’t provided, Django will use the value of the `EMAIL_HOST_PASSWORD` setting.
- `connection`: The optional email backend to use to send the mail. If unspecified, an instance of the default backend will be used. See the documentation on *Email backends* for more details.
- `html_message`: If `html_message` is provided, the resulting email will be a *multipart/alternative* email with `message` as the *text/plain* content type and `html_message` as the *text/html* content type.

The return value will be the number of successfully delivered messages (which can be 0 or 1 since it can only send one message).

### 3.14.3 `send_mass_mail()`

`send_mass_mail` (*datatuple*, *fail\_silently=False*, *auth\_user=None*, *auth\_password=None*, *connection=None*)

`django.core.mail.send_mass_mail()` is intended to handle mass emailing.

`datatuple` is a tuple in which each element is in this format:

```
(subject, message, from_email, recipient_list)
```

`fail_silently`, `auth_user` and `auth_password` have the same functions as in `send_mail()`.

Each separate element of `datatuple` results in a separate email message. As in `send_mail()`, recipients in the same `recipient_list` will all see the other addresses in the email messages’ “To:” field.

For example, the following code would send two different messages to two different sets of recipients; however, only one connection to the mail server would be opened:

```
message1 = ('Subject here', 'Here is the message', 'from@example.com', [
    ↪ 'first@example.com', 'other@example.com'])
message2 = ('Another Subject', 'Here is another message', 'from@example.com', [
    ↪ 'second@test.com'])
send_mass_mail((message1, message2), fail_silently=False)
```

The return value will be the number of successfully delivered messages.

### `send_mass_mail()` vs. `send_mail()`

The main difference between `send_mass_mail()` and `send_mail()` is that `send_mail()` opens a connection to the mail server each time it's executed, while `send_mass_mail()` uses a single connection for all of its messages. This makes `send_mass_mail()` slightly more efficient.

### 3.14.4 `mail_admins()`

**`mail_admins`** (*subject, message, fail\_silently=False, connection=None, html\_message=None*)

`django.core.mail.mail_admins()` is a shortcut for sending an email to the site admins, as defined in the `ADMINS` setting.

`mail_admins()` prefixes the subject with the value of the `EMAIL_SUBJECT_PREFIX` setting, which is "[Django] " by default.

The "From:" header of the email will be the value of the `SERVER_EMAIL` setting.

This method exists for convenience and readability.

If `html_message` is provided, the resulting email will be a *multipart/alternative* email with `message` as the *text/plain* content type and `html_message` as the *text/html* content type.

### 3.14.5 `mail_managers()`

**`mail_managers`** (*subject, message, fail\_silently=False, connection=None, html\_message=None*)

`django.core.mail.mail_managers()` is just like `mail_admins()`, except it sends an email to the site managers, as defined in the `MANAGERS` setting.

### 3.14.6 Examples

This sends a single email to `john@example.com` and `jane@example.com`, with them both appearing in the "To:":

```
send_mail(
    'Subject',
    'Message.',
    'from@example.com',
    ['john@example.com', 'jane@example.com'],
)
```

This sends a message to `john@example.com` and `jane@example.com`, with them both receiving a separate email:

```
datatuple = (
    ('Subject', 'Message.', 'from@example.com', ['john@example.com']),
    ('Subject', 'Message.', 'from@example.com', ['jane@example.com']),
)
send_mass_mail(datatuple)
```

### 3.14.7 Preventing header injection

**Header injection** is a security exploit in which an attacker inserts extra email headers to control the "To:" and "From:" in email messages that your scripts generate.

The Django email functions outlined above all protect against header injection by forbidding newlines in header values. If any `subject`, `from_email` or `recipient_list` contains a newline (in either Unix, Windows or Mac style), the email function (e.g. `send_mail()`) will raise `django.core.mail.BadHeaderError` (a subclass of `ValueError`) and, hence, will not send the email. It's your responsibility to validate all data before passing it to the email functions.

If a message contains headers at the start of the string, the headers will simply be printed as the first bit of the email message.

Here's an example view that takes a `subject`, `message` and `from_email` from the request's POST data, sends that to `admin@example.com` and redirects to `"/contact/thanks/"` when it's done:

```
from django.core.mail import send_mail, BadHeaderError
from django.http import HttpResponseRedirect

def send_email(request):
    subject = request.POST.get('subject', '')
    message = request.POST.get('message', '')
    from_email = request.POST.get('from_email', '')
    if subject and message and from_email:
        try:
            send_mail(subject, message, from_email, ['admin@example.com'])
        except BadHeaderError:
            return HttpResponseRedirect('/contact/thanks/')
        return HttpResponseRedirect('/contact/thanks/')
    else:
        # In reality we'd use a form class
        # to get proper validation errors.
        return HttpResponseRedirect('Make sure all fields are entered and valid.')
```

### 3.14.8 The `EmailMessage` class

Django's `send_mail()` and `send_mass_mail()` functions are actually thin wrappers that make use of the `EmailMessage` class.

Not all features of the `EmailMessage` class are available through the `send_mail()` and related wrapper functions. If you wish to use advanced features, such as BCC'ed recipients, file attachments, or multi-part email, you'll need to create `EmailMessage` instances directly.

---

**Note:** This is a design feature. `send_mail()` and related functions were originally the only interface Django provided. However, the list of parameters they accepted was slowly growing over time. It made sense to move to a more object-oriented design for email messages and retain the original functions only for backwards compatibility.

---

`EmailMessage` is responsible for creating the email message itself. The `email backend` is then responsible for sending the email.

For convenience, `EmailMessage` provides a simple `send()` method for sending a single email. If you need to send multiple messages, the email backend API *provides an alternative*.

#### EmailMessage Objects

##### class `EmailMessage`

The `EmailMessage` class is initialized with the following parameters (in the given order, if positional arguments are used). All parameters are optional and can be set at any time prior to calling the `send()` method.

- `subject`: The subject line of the email.
- `body`: The body text. This should be a plain text message.
- `from_email`: The sender's address. Both `fred@example.com` and `Fred <fred@example.com>` forms are legal. If omitted, the `DEFAULT_FROM_EMAIL` setting is used.
- `to`: A list or tuple of recipient addresses.
- `bcc`: A list or tuple of addresses used in the “Bcc” header when sending the email.
- `connection`: An email backend instance. Use this parameter if you want to use the same connection for multiple messages. If omitted, a new connection is created when `send()` is called.
- `attachments`: A list of attachments to put on the message. These can be either `email.MIMEBase.MIMEBase` instances, or `(filename, content, mimetype)` triples.
- `headers`: A dictionary of extra headers to put on the message. The keys are the header name, values are the header values. It's up to the caller to ensure header names and values are in the correct format for an email message. The corresponding attribute is `extra_headers`.
- `cc`: A list or tuple of recipient addresses used in the “Cc” header when sending the email.
- `reply_to`: A list or tuple of recipient addresses used in the “Reply-To” header when sending the email.

For example:

```
from django.core.mail import EmailMessage

email = EmailMessage(
    'Hello',
    'Body goes here',
    'from@example.com',
    ['to1@example.com', 'to2@example.com'],
    ['bcc@example.com'],
    reply_to=['another@example.com'],
    headers={'Message-ID': 'foo'},
)
```

The class has the following methods:

- `send(fail_silently=False)` sends the message. If a connection was specified when the email was constructed, that connection will be used. Otherwise, an instance of the default backend will be instantiated and used. If the keyword argument `fail_silently` is `True`, exceptions raised while sending the message will be quashed. An empty list of recipients will not raise an exception.
- `message()` constructs a `django.core.mail.SafeMIMEText` object (a subclass of Python's `email.MIMEText.MIMEText` class) or a `django.core.mail.SafeMIMEMultipart` object holding the message to be sent. If you ever need to extend the `EmailMessage` class, you'll probably want to override this method to put the content you want into the MIME object.
- `recipients()` returns a list of all the recipients of the message, whether they're recorded in the `to`, `cc` or `bcc` attributes. This is another method you might need to override when subclassing, because the SMTP server needs to be told the full list of recipients when the message is sent. If you add another way to specify recipients in your class, they need to be returned from this method as well.
- `attach()` creates a new file attachment and adds it to the message. There are two ways to call `attach()`:
  - You can pass it a single argument that is an `email.MIMEBase.MIMEBase` instance. This will be inserted directly into the resulting message.
  - Alternatively, you can pass `attach()` three arguments: `filename`, `content` and `mimetype`. `filename` is the name of the file attachment as it will appear in the email, `content` is the data that

will be contained inside the attachment and `mimetype` is the optional MIME type for the attachment. If you omit `mimetype`, the MIME content type will be guessed from the filename of the attachment.

For example:

```
message.attach('design.png', img_data, 'image/png')
```

If you specify a `mimetype` of `message/rfc822`, it will also accept `django.core.mail.EmailMessage` and `email.message.Message`.

In addition, `message/rfc822` attachments will no longer be base64-encoded in violation of **RFC 2046#section-5.2.1**, which can cause issues with displaying the attachments in *Evolution* and *Thunderbird*.

- `attach_file()` creates a new attachment using a file from your filesystem. Call it with the path of the file to attach and, optionally, the MIME type to use for the attachment. If the MIME type is omitted, it will be guessed from the filename. The simplest use would be:

```
message.attach_file('/images/weather_map.png')
```

### Sending alternative content types

It can be useful to include multiple versions of the content in an email; the classic example is to send both text and HTML versions of a message. With Django's email library, you can do this using the `EmailMultiAlternatives` class. This subclass of `EmailMessage` has an `attach_alternative()` method for including extra versions of the message body in the email. All the other methods (including the class initialization) are inherited directly from `EmailMessage`.

To send a text and HTML combination, you could write:

```
from django.core.mail import EmailMultiAlternatives

subject, from_email, to = 'hello', 'from@example.com', 'to@example.com'
text_content = 'This is an important message.'
html_content = '<p>This is an <strong>important</strong> message.</p>'
msg = EmailMultiAlternatives(subject, text_content, from_email, [to])
msg.attach_alternative(html_content, "text/html")
msg.send()
```

By default, the MIME type of the `body` parameter in an `EmailMessage` is `"text/plain"`. It is good practice to leave this alone, because it guarantees that any recipient will be able to read the email, regardless of their mail client. However, if you are confident that your recipients can handle an alternative content type, you can use the `content_subtype` attribute on the `EmailMessage` class to change the main content type. The major type will always be `"text"`, but you can change the subtype. For example:

```
msg = EmailMessage(subject, html_content, from_email, [to])
msg.content_subtype = "html" # Main content is now text/html
msg.send()
```

### 3.14.9 Email backends

The actual sending of an email is handled by the email backend.

The email backend class has the following methods:

- `open()` instantiates a long-lived email-sending connection.

- `close()` closes the current email-sending connection.
- `send_messages(email_messages)` sends a list of *EmailMessage* objects. If the connection is not open, this call will implicitly open the connection, and close the connection afterwards. If the connection is already open, it will be left open after mail has been sent.

It can also be used as a context manager, which will automatically call `open()` and `close()` as needed:

```
from django.core import mail

with mail.get_connection() as connection:
    mail.EmailMessage(
        subject1, body1, from1, [to1],
        connection=connection,
    ).send()
    mail.EmailMessage(
        subject2, body2, from2, [to2],
        connection=connection,
    ).send()
```

## Obtaining an instance of an email backend

The `get_connection()` function in `django.core.mail` returns an instance of the email backend that you can use.

**get\_connection** (*backend=None, fail\_silently=False, \*args, \*\*kwargs*)

By default, a call to `get_connection()` will return an instance of the email backend specified in `EMAIL_BACKEND`. If you specify the `backend` argument, an instance of that backend will be instantiated.

The `fail_silently` argument controls how the backend should handle errors. If `fail_silently` is `True`, exceptions during the email sending process will be silently ignored.

All other arguments are passed directly to the constructor of the email backend.

Django ships with several email sending backends. With the exception of the SMTP backend (which is the default), these backends are only useful during testing and development. If you have special email sending requirements, you can *write your own email backend*.

## SMTP backend

**class** `backends.smtp.EmailBackend` (*host=None, port=None, username=None, password=None, use\_tls=None, fail\_silently=False, use\_ssl=None, timeout=None, ssl\_keyfile=None, ssl\_certfile=None, \*\*kwargs*)

This is the default backend. Email will be sent through a SMTP server.

The value for each argument is retrieved from the matching setting if the argument is `None`:

- `host`: `EMAIL_HOST`
- `port`: `EMAIL_PORT`
- `username`: `EMAIL_HOST_USER`
- `password`: `EMAIL_HOST_PASSWORD`
- `use_tls`: `EMAIL_USE_TLS`
- `use_ssl`: `EMAIL_USE_SSL`
- `timeout`: `EMAIL_TIMEOUT`

- `ssl_keyfile`: `EMAIL_SSL_KEYFILE`
- `ssl_certfile`: `EMAIL_SSL_CERTFILE`

The SMTP backend is the default configuration inherited by Django. If you want to specify it explicitly, put the following in your settings:

```
EMAIL_BACKEND = 'django.core.mail.backends.smtp.EmailBackend'
```

If unspecified, the default `timeout` will be the one provided by `socket.getdefaulttimeout()`, which defaults to `None` (no timeout).

### Console backend

Instead of sending out real emails the console backend just writes the emails that would be sent to the standard output. By default, the console backend writes to `stdout`. You can use a different stream-like object by providing the `stream` keyword argument when constructing the connection.

To specify this backend, put the following in your settings:

```
EMAIL_BACKEND = 'django.core.mail.backends.console.EmailBackend'
```

This backend is not intended for use in production – it is provided as a convenience that can be used during development.

### File backend

The file backend writes emails to a file. A new file is created for each new session that is opened on this backend. The directory to which the files are written is either taken from the `EMAIL_FILE_PATH` setting or from the `file_path` keyword when creating a connection with `get_connection()`.

To specify this backend, put the following in your settings:

```
EMAIL_BACKEND = 'django.core.mail.backends.filebased.EmailBackend'  
EMAIL_FILE_PATH = '/tmp/app-messages' # change this to a proper location
```

This backend is not intended for use in production – it is provided as a convenience that can be used during development.

### In-memory backend

The `'locmem'` backend stores messages in a special attribute of the `django.core.mail` module. The `outbox` attribute is created when the first message is sent. It's a list with an `EmailMessage` instance for each message that would be sent.

To specify this backend, put the following in your settings:

```
EMAIL_BACKEND = 'django.core.mail.backends.locmem.EmailBackend'
```

This backend is not intended for use in production – it is provided as a convenience that can be used during development and testing.

## Dummy backend

As the name suggests the dummy backend does nothing with your messages. To specify this backend, put the following in your settings:

```
EMAIL_BACKEND = 'django.core.mail.backends.dummy.EmailBackend'
```

This backend is not intended for use in production – it is provided as a convenience that can be used during development.

## Defining a custom email backend

If you need to change how emails are sent you can write your own email backend. The `EMAIL_BACKEND` setting in your settings file is then the Python import path for your backend class.

Custom email backends should subclass `BaseEmailBackend` that is located in the `django.core.mail.backends.base` module. A custom email backend must implement the `send_messages(email_messages)` method. This method receives a list of `EmailMessage` instances and returns the number of successfully delivered messages. If your backend has any concept of a persistent session or connection, you should also implement the `open()` and `close()` methods. Refer to `smtp.EmailBackend` for a reference implementation.

## Sending multiple emails

Establishing and closing an SMTP connection (or any other network connection, for that matter) is an expensive process. If you have a lot of emails to send, it makes sense to reuse an SMTP connection, rather than creating and destroying a connection every time you want to send an email.

There are two ways you tell an email backend to reuse a connection.

Firstly, you can use the `send_messages()` method. `send_messages()` takes a list of `EmailMessage` instances (or subclasses), and sends them all using a single connection.

For example, if you have a function called `get_notification_email()` that returns a list of `EmailMessage` objects representing some periodic email you wish to send out, you could send these emails using a single call to `send_messages()`:

```
from django.core import mail
connection = mail.get_connection() # Use default email connection
messages = get_notification_email()
connection.send_messages(messages)
```

In this example, the call to `send_messages()` opens a connection on the backend, sends the list of messages, and then closes the connection again.

The second approach is to use the `open()` and `close()` methods on the email backend to manually control the connection. `send_messages()` will not manually open or close the connection if it is already open, so if you manually open the connection, you can control when it is closed. For example:

```
from django.core import mail
connection = mail.get_connection()

# Manually open the connection
connection.open()

# Construct an email message that uses the connection
email = mail.EmailMessage(
```

```

    'Hello',
    'Body goes here',
    'from@example.com',
    ['to1@example.com'],
    connection=connection,
)
email1.send() # Send the email

# Construct two more messages
email2 = mail.EmailMessage(
    'Hello',
    'Body goes here',
    'from@example.com',
    ['to2@example.com'],
)
email3 = mail.EmailMessage(
    'Hello',
    'Body goes here',
    'from@example.com',
    ['to3@example.com'],
)

# Send the two emails in a single call -
connection.send_messages([email2, email3])
# The connection was already open so send_messages() doesn't close it.
# We need to manually close the connection.
connection.close()

```

### 3.14.10 Configuring email for development

There are times when you do not want Django to send emails at all. For example, while developing a website, you probably don't want to send out thousands of emails – but you may want to validate that emails will be sent to the right people under the right conditions, and that those emails will contain the correct content.

The easiest way to configure email for local development is to use the *console* email backend. This backend redirects all email to stdout, allowing you to inspect the content of mail.

The *file* email backend can also be useful during development – this backend dumps the contents of every SMTP connection to a file that can be inspected at your leisure.

Another approach is to use a “dumb” SMTP server that receives the emails locally and displays them to the terminal, but does not actually send anything. Python has a built-in way to accomplish this with a single command:

```
python -m smtpd -n -c DebuggingServer localhost:1025
```

This command will start a simple SMTP server listening on port 1025 of localhost. This server simply prints to standard output all email headers and the email body. You then only need to set the *EMAIL\_HOST* and *EMAIL\_PORT* accordingly. For a more detailed discussion of SMTP server options, see the Python documentation for the `smtpd` module.

For information about unit-testing the sending of emails in your application, see the *Email services* section of the testing documentation.

## 3.15 Internationalization and localization

### 3.15.1 Translation

#### Overview

In order to make a Django project translatable, you have to add a minimal number of hooks to your Python code and templates. These hooks are called *translation strings*. They tell Django: “This text should be translated into the end user’s language, if a translation for this text is available in that language.” It’s your responsibility to mark translatable strings; the system can only translate strings it knows about.

Django then provides utilities to extract the translation strings into a *message file*. This file is a convenient way for translators to provide the equivalent of the translation strings in the target language. Once the translators have filled in the message file, it must be compiled. This process relies on the GNU gettext toolset.

Once this is done, Django takes care of translating Web apps on the fly in each available language, according to users’ language preferences.

Django’s internationalization hooks are on by default, and that means there’s a bit of i18n-related overhead in certain places of the framework. If you don’t use internationalization, you should take the two seconds to set `USE_I18N = False` in your settings file. Then Django will make some optimizations so as not to load the internationalization machinery.

---

**Note:** There is also an independent but related `USE_L10N` setting that controls if Django should implement format localization. See *Format localization* for more details.

---

---

**Note:** Make sure you’ve activated translation for your project (the fastest way is to check if `MIDDLEWARE` includes `django.middleware.locale.LocaleMiddleware`). If you haven’t yet, see *How Django discovers language preference*.

---

#### Internationalization: in Python code

##### Standard translation

Specify a translation string by using the function `ugettext()`. It’s convention to import this as a shorter alias, `_`, to save typing.

---

**Note:** Python’s standard library `gettext` module installs `_()` into the global namespace, as an alias for `gettext()`. In Django, we have chosen not to follow this practice, for a couple of reasons:

1. For international character set (Unicode) support, `ugettext()` is more useful than `gettext()`. Sometimes, you should be using `ugettext_lazy()` as the default translation method for a particular file. Without `_()` in the global namespace, the developer has to think about which is the most appropriate translation function.
  2. The underscore character (`_`) is used to represent “the previous result” in Python’s interactive shell and doctest tests. Installing a global `_()` function causes interference. Explicitly importing `ugettext()` as `_()` avoids this problem.
- 

#### What functions may be aliased as `_`?

Because of how `xgettext` (used by `makemessages`) works, only functions that take a single string argument can be imported as `_`:

- `gettext()`
- `gettext_lazy()`
- `ugettext()`
- `ugettext_lazy()`

In this example, the text "Welcome to my site." is marked as a translation string:

```
from django.utils.translation import ugettext as _
from django.http import HttpResponse

def my_view(request):
    output = _("Welcome to my site.")
    return HttpResponse(output)
```

Obviously, you could code this without using the alias. This example is identical to the previous one:

```
from django.utils.translation import gettext
from django.http import HttpResponse

def my_view(request):
    output = gettext("Welcome to my site.")
    return HttpResponse(output)
```

Translation works on computed values. This example is identical to the previous two:

```
def my_view(request):
    words = ['Welcome', 'to', 'my', 'site.']
    output = _(' '.join(words))
    return HttpResponse(output)
```

Translation works on variables. Again, here's an identical example:

```
def my_view(request):
    sentence = 'Welcome to my site.'
    output = _(sentence)
    return HttpResponse(output)
```

(The caveat with using variables or computed values, as in the previous two examples, is that Django's translation-string-detecting utility, `django-admin makemessages`, won't be able to find these strings. More on `makemessages` later.)

The strings you pass to `_()` or `ugettext()` can take placeholders, specified with Python's standard named-string interpolation syntax. Example:

```
def my_view(request, m, d):
    output = _('Today is %(month)s %(day)s.') % {'month': m, 'day': d}
    return HttpResponse(output)
```

This technique lets language-specific translations reorder the placeholder text. For example, an English translation may be "Today is November 26.", while a Spanish translation may be "Hoy es 26 de Noviembre." – with the month and the day placeholders swapped.

For this reason, you should use named-string interpolation (e.g., `%(day)s`) instead of positional interpolation (e.g., `%s` or `%d`) whenever you have more than a single parameter. If you used positional interpolation, translations wouldn't be able to reorder placeholder text.

## Comments for translators

If you would like to give translators hints about a translatable string, you can add a comment prefixed with the `Translators` keyword on the line preceding the string, e.g.:

```
def my_view(request):
    # Translators: This message appears on the home page only
    output = ugettext("Welcome to my site.")
```

The comment will then appear in the resulting `.po` file associated with the translatable construct located below it and should also be displayed by most translation tools.

---

**Note:** Just for completeness, this is the corresponding fragment of the resulting `.po` file:

```
#. Translators: This message appears on the home page only
# path/to/python/file.py:123
msgid "Welcome to my site."
msgstr ""
```

---

This also works in templates. See *Comments for translators in templates* for more details.

## Marking strings as no-op

Use the function `django.utils.translation.ugettext_noop()` to mark a string as a translation string without translating it. The string is later translated from a variable.

Use this if you have constant strings that should be stored in the source language because they are exchanged over systems or users – such as strings in a database – but should be translated at the last possible point in time, such as when the string is presented to the user.

## Pluralization

Use the function `django.utils.translation.ungettext()` to specify pluralized messages.

`ungettext` takes three arguments: the singular translation string, the plural translation string and the number of objects.

This function is useful when you need your Django application to be localizable to languages where the number and complexity of [plural forms](#) is greater than the two forms used in English ('object' for the singular and 'objects' for all the cases where `count` is different from one, irrespective of its value.)

For example:

```
from django.utils.translation import ungettext
from django.http import HttpResponse

def hello_world(request, count):
    page = ungettext(
        'there is %(count)d object',
```

```

        'there are %(count)d objects',
    count) % {
        'count': count,
    }
    return HttpResponse(page)

```

In this example the number of objects is passed to the translation languages as the `count` variable.

Note that pluralization is complicated and works differently in each language. Comparing `count` to 1 isn't always the correct rule. This code looks sophisticated, but will produce incorrect results for some languages:

```

from django.utils.translation import ungettext
from myapp.models import Report

count = Report.objects.count()
if count == 1:
    name = Report._meta.verbose_name
else:
    name = Report._meta.verbose_name_plural

text = ungettext(
    'There is %(count)d %(name)s available.',
    'There are %(count)d %(name)s available.',
    count
) % {
    'count': count,
    'name': name
}

```

Don't try to implement your own singular-or-plural logic, it won't be correct. In a case like this, consider something like the following:

```

text = ungettext(
    'There is %(count)d %(name)s object available.',
    'There are %(count)d %(name)s objects available.',
    count
) % {
    'count': count,
    'name': Report._meta.verbose_name,
}

```

**Note:** When using `ungettext()`, make sure you use a single name for every extrapolated variable included in the literal. In the examples above, note how we used the `name` Python variable in both translation strings. This example, besides being incorrect in some languages as noted above, would fail:

```

text = ungettext(
    'There is %(count)d %(name)s available.',
    'There are %(count)d %(plural_name)s available.',
    count
) % {
    'count': Report.objects.count(),
    'name': Report._meta.verbose_name,
    'plural_name': Report._meta.verbose_name_plural
}

```

You would get an error when running `django-admin compilemessages`:

```
a format specification for argument 'name', as in 'msgstr[0]', doesn't exist in 'msgid  
↪'
```

---

**Note:** Plural form and po files

Django does not support custom plural equations in po files. As all translation catalogs are merged, only the plural form for the main Django po file (in `django/conf/locale/<lang_code>/LC_MESSAGES/django.po`) is considered. Plural forms in all other po files are ignored. Therefore, you should not use different plural equations in your project or application po files.

---

## Contextual markers

Sometimes words have several meanings, such as "May" in English, which refers to a month name and to a verb. To enable translators to translate these words correctly in different contexts, you can use the `django.utils.translation.pgettext()` function, or the `django.utils.translation.npgettext()` function if the string needs pluralization. Both take a context string as the first variable.

In the resulting `.po` file, the string will then appear as often as there are different contextual markers for the same string (the context will appear on the `msgctxt` line), allowing the translator to give a different translation for each of them.

For example:

```
from django.utils.translation import pgettext  
  
month = pgettext("month name", "May")
```

or:

```
from django.db import models  
from django.utils.translation import pgettext_lazy  
  
class MyThing(models.Model):  
    name = models.CharField(help_text=pgettext_lazy(  
        'help text for MyThing model', 'This is the help text'))
```

will appear in the `.po` file as:

```
msgctxt "month name"  
msgid "May"  
msgstr ""
```

Contextual markers are also supported by the `trans` and `blocktrans` template tags.

## Lazy translation

Use the lazy versions of translation functions in `django.utils.translation` (easily recognizable by the `lazy` suffix in their names) to translate strings lazily – when the value is accessed rather than when they're called.

These functions store a lazy reference to the string – not the actual translation. The translation itself will be done when the string is used in a string context, such as in template rendering.

This is essential when calls to these functions are located in code paths that are executed at module load time.

This is something that can easily happen when defining models, forms and model forms, because Django implements these such that their fields are actually class-level attributes. For that reason, make sure to use lazy translations in the following cases:

### Model fields and relationships `verbose_name` and `help_text` option values

For example, to translate the help text of the `name` field in the following model, do the following:

```
from django.db import models
from django.utils.translation import ugettext_lazy as _

class MyThing(models.Model):
    name = models.CharField(help_text=_('This is the help text'))
```

You can mark names of `ForeignKey`, `ManyToManyField` or `OneToOneField` relationship as translatable by using their `verbose_name` options:

```
class MyThing(models.Model):
    kind = models.ForeignKey(
        ThingKind,
        on_delete=models.CASCADE,
        related_name='kinds',
        verbose_name=_('kind'),
    )
```

Just like you would do in `verbose_name` you should provide a lowercase verbose name text for the relation as Django will automatically titlecase it when required.

### Model verbose names values

It is recommended to always provide explicit `verbose_name` and `verbose_name_plural` options rather than relying on the fallback English-centric and somewhat naïve determination of verbose names Django performs by looking at the model's class name:

```
from django.db import models
from django.utils.translation import ugettext_lazy as _

class MyThing(models.Model):
    name = models.CharField(_('name'), help_text=_('This is the help text'))

    class Meta:
        verbose_name = _('my thing')
        verbose_name_plural = _('my things')
```

### Model methods `short_description` attribute values

For model methods, you can provide translations to Django and the admin site with the `short_description` attribute:

```
from django.db import models
from django.utils.translation import ugettext_lazy as _

class MyThing(models.Model):
```

```
kind = models.ForeignKey(
    ThingKind,
    on_delete=models.CASCADE,
    related_name='kinds',
    verbose_name=_('kind'),
)

def is_mouse(self):
    return self.kind.type == MOUSE_TYPE
is_mouse.short_description = _('Is it a mouse?')
```

## Working with lazy translation objects

The result of a `ugettext_lazy()` call can be used wherever you would use a unicode string (a `str` object) in other Django code, but it may not work with arbitrary Python code. For example, the following won't work because the `requests` library doesn't handle `ugettext_lazy` objects:

```
body = ugettext_lazy("I \u2764 Django") # (unicode :heart:)
requests.post('https://example.com/send', data={'body': body})
```

You can avoid such problems by casting `ugettext_lazy()` objects to text strings before passing them to non-Django code:

```
requests.post('https://example.com/send', data={'body': str(body)})
```

Use `unicode` in place of `str` on Python 2, or `six.text_type` to support Python 2 and 3.

If you try to use a `ugettext_lazy()` result where a bytestring (a `bytes` object) is expected, things won't work as expected since a `ugettext_lazy()` object doesn't know how to convert itself to a bytestring. You can't use a unicode string inside a bytestring, either, so this is consistent with normal Python behavior. For example, putting a unicode proxy into a unicode string is fine:

```
"Hello %s" % ugettext_lazy("people")
```

But you can't insert a unicode object into a bytestring and nor can you insert a unicode proxy there:

```
b"Hello %s" % ugettext_lazy("people")
```

If you ever see output that looks like `"hello <django.utils.functional...>"`, you have tried to insert the result of `ugettext_lazy()` into a bytestring. That's a bug in your code.

If you don't like the long `ugettext_lazy` name, you can just alias it as `_` (underscore), like so:

```
from django.db import models
from django.utils.translation import ugettext_lazy as _

class MyThing(models.Model):
    name = models.CharField(help_text=_('This is the help text'))
```

Using `ugettext_lazy()` and `ungettext_lazy()` to mark strings in models and utility functions is a common operation. When you're working with these objects elsewhere in your code, you should ensure that you don't accidentally convert them to strings, because they should be converted as late as possible (so that the correct locale is in effect). This necessitates the use of the helper function described next.

## Lazy translations and plural

When using lazy translation for a plural string (`[u]n[p]gettext_lazy`), you generally don't know the number argument at the time of the string definition. Therefore, you are authorized to pass a key name instead of an integer as the number argument. Then `number` will be looked up in the dictionary under that key during string interpolation. Here's example:

```
from django import forms
from django.utils.translation import ungettext_lazy

class MyForm(forms.Form):
    error_message = ungettext_lazy("You only provided %(num)d argument",
                                   "You only provided %(num)d arguments", 'num')

    def clean(self):
        # ...
        if error:
            raise forms.ValidationError(self.error_message % {'num': number})
```

If the string contains exactly one unnamed placeholder, you can interpolate directly with the number argument:

```
class MyForm(forms.Form):
    error_message = ungettext_lazy(
        "You provided %d argument",
        "You provided %d arguments",
    )

    def clean(self):
        # ...
        if error:
            raise forms.ValidationError(self.error_message % number)
```

## Joining strings: `string_concat()`

Standard Python string joins (`' '.join(...)`) will not work on lists containing lazy translation objects. Instead, you can use `django.utils.translation.string_concat()`, which creates a lazy object that concatenates its contents *and* converts them to strings only when the result is included in a string. For example:

```
from django.utils.translation import string_concat
from django.utils.translation import ugettext_lazy
...
name = ugettext_lazy('John Lennon')
instrument = ugettext_lazy('guitar')
result = string_concat(name, ': ', instrument)
```

In this case, the lazy translations in `result` will only be converted to strings when `result` itself is used in a string (usually at template rendering time).

## Other uses of lazy in delayed translations

For any other case where you would like to delay the translation, but have to pass the translatable string as argument to another function, you can wrap this function inside a lazy call yourself. For example:

```
from django.utils import six # Python 3 compatibility
from django.utils.functional import lazy
from django.utils.safestring import mark_safe
from django.utils.translation import ugettext_lazy as _

mark_safe_lazy = lazy(mark_safe, six.text_type)
```

And then later:

```
lazy_string = mark_safe_lazy_("<p>My <strong>string!</strong></p>")
```

## Localized names of languages

### `get_language_info()`

The `get_language_info()` function provides detailed information about languages:

```
>>> from django.utils.translation import activate, get_language_info
>>> activate('fr')
>>> li = get_language_info('de')
>>> print(li['name'], li['name_local'], li['name_translated'], li['bidi'])
German Deutsch Allemand False
```

The `name`, `name_local`, and `name_translated` attributes of the dictionary contain the name of the language in English, in the language itself, and in your current active language respectively. The `bidi` attribute is `True` only for bi-directional languages.

The source of the language information is the `django.conf.locale` module. Similar access to this information is available for template code. See below.

The `'name_translated'` attribute was added.

## Internationalization: in template code

Translations in *Django templates* uses two template tags and a slightly different syntax than in Python code. To give your template access to these tags, put `{% load i18n %}` toward the top of your template. As with all template tags, this tag needs to be loaded in all templates which use translations, even those templates that extend from other templates which have already loaded the `i18n` tag.

### `trans` template tag

The `{% trans %}` template tag translates either a constant string (enclosed in single or double quotes) or variable content:

```
<title>{% trans "This is the title." %}</title>
<title>{% trans myvar %}</title>
```

If the `noop` option is present, variable lookup still takes place but the translation is skipped. This is useful when “stubbing out” content that will require translation in the future:

```
<title>{% trans "myvar" noop %}</title>
```

Internally, inline translations use an `ugettext()` call.

In case a template var (`myvar` above) is passed to the tag, the tag will first resolve such variable to a string at run-time and then look up that string in the message catalogs.

It's not possible to mix a template variable inside a string within `{% trans %}`. If your translations require strings with variables (placeholders), use `{% blocktrans %}` instead.

If you'd like to retrieve a translated string without displaying it, you can use the following syntax:

```
{% trans "This is the title" as the_title %}

<title>{{ the_title }}</title>
<meta name="description" content="{{ the_title }}">
```

In practice you'll use this to get a string you can use in multiple places in a template or so you can use the output as an argument for other template tags or filters:

```
{% trans "starting point" as start %}
{% trans "end point" as end %}
{% trans "La Grande Boucle" as race %}

<h1>
  <a href="/" title="{% blocktrans %}Back to '{{ race }}' homepage{% endblocktrans %}"
  <=>{{ race }}</a>
</h1>
<p>
  {% for stage in tour_stages %}
    {% cycle start end %}: {{ stage }}{% if forloop.counter|divisibleby:2 %}<br />{%_
  <=>else %}, {% endif %}
  {% endfor %}
</p>
```

`{% trans %}` also supports *contextual markers* using the `context` keyword:

```
{% trans "May" context "month name" %}
```

### blocktrans template tag

Contrarily to the `trans` tag, the `blocktrans` tag allows you to mark complex sentences consisting of literals and variable content for translation by making use of placeholders:

```
{% blocktrans %}This string will have {{ value }} inside.{% endblocktrans %}
```

To translate a template expression – say, accessing object attributes or using template filters – you need to bind the expression to a local variable for use within the translation block. Examples:

```
{% blocktrans with amount=article.price %}
That will cost $ {{ amount }}.
{% endblocktrans %}

{% blocktrans with myvar=value|filter %}
This will have {{ myvar }} inside.
{% endblocktrans %}
```

You can use multiple expressions inside a single `blocktrans` tag:

```
{% blocktrans with book_t=book|title author_t=author|title %}
This is {{ book_t }} by {{ author_t }}
{% endblocktrans %}
```

**Note:** The previous more verbose format is still supported: `{% blocktrans with book|title as book_t and author|title as author_t %}`

---

Other block tags (for example `{% for %}` or `{% if %}`) are not allowed inside a `blocktrans` tag.

If resolving one of the block arguments fails, `blocktrans` will fall back to the default language by deactivating the currently active language temporarily with the `deactivate_all()` function.

This tag also provides for pluralization. To use it:

- Designate and bind a counter value with the name `count`. This value will be the one used to select the right plural form.
- Specify both the singular and plural forms separating them with the `{% plural %}` tag within the `{% blocktrans %}` and `{% endblocktrans %}` tags.

An example:

```
{% blocktrans count counter=list|length %}
There is only one {{ name }} object.
{% plural %}
There are {{ counter }} {{ name }} objects.
{% endblocktrans %}
```

A more complex example:

```
{% blocktrans with amount=article.price count years=i.length %}
That will cost $ {{ amount }} per year.
{% plural %}
That will cost $ {{ amount }} per {{ years }} years.
{% endblocktrans %}
```

When you use both the pluralization feature and bind values to local variables in addition to the counter value, keep in mind that the `blocktrans` construct is internally converted to an `ungettext` call. This means the same *notes regarding ungettext variables* apply.

Reverse URL lookups cannot be carried out within the `blocktrans` and should be retrieved (and stored) beforehand:

```
{% url 'path.to.view' arg arg2 as the_url %}
{% blocktrans %}
This is a URL: {{ the_url }}
{% endblocktrans %}
```

If you'd like to retrieve a translated string without displaying it, you can use the following syntax:

```
{% blocktrans asvar the_title %}The title is {{ title }}.{% endblocktrans %}
<title>{{ the_title }}</title>
<meta name="description" content="{{ the_title }}">
```

In practice you'll use this to get a string you can use in multiple places in a template or so you can use the output as an argument for other template tags or filters.

The `asvar` syntax was added.

`{% blocktrans %}` also supports *contextual markers* using the `context` keyword:

```
{% blocktrans with name=user.username context "greeting" %}Hi {{ name }}{%
endblocktrans %}
```

Another feature `{% blocktrans %}` supports is the `trimmed` option. This option will remove newline characters from the beginning and the end of the content of the `{% blocktrans %}` tag, replace any whitespace at the beginning and end of a line and merge all lines into one using a space character to separate them. This is quite useful for indenting the content of a `{% blocktrans %}` tag without having the indentation characters end up in the corresponding entry in the PO file, which makes the translation process easier.

For instance, the following `{% blocktrans %}` tag:

```
{% blocktrans trimmed %}
  First sentence.
  Second paragraph.
{% endblocktrans %}
```

will result in the entry "First sentence. Second paragraph." in the PO file, compared to "\n First sentence.\n Second sentence.\n", if the `trimmed` option had not been specified.

### String literals passed to tags and filters

You can translate string literals passed as arguments to tags and filters by using the familiar `_()` syntax:

```
{% some_tag _("Page not found") value|yesno:_("yes,no") %}
```

In this case, both the tag and the filter will see the translated string, so they don't need to be aware of translations.

**Note:** In this example, the translation infrastructure will be passed the string "yes,no", not the individual strings "yes" and "no". The translated string will need to contain the comma so that the filter parsing code knows how to split up the arguments. For example, a German translator might translate the string "yes,no" as "ja,nein" (keeping the comma intact).

### Comments for translators in templates

Just like with *Python code*, these notes for translators can be specified using comments, either with the `comment` tag:

```
{% comment %}Translators: View verb{% endcomment %}
{% trans "View" %}

{% comment %}Translators: Short intro blurb{% endcomment %}
<p>{% blocktrans %}A multiline translatable
literal.{% endblocktrans %}</p>
```

or with the `{# ... #}` *one-line comment constructs*:

```
{# Translators: Label of a button that triggers search #}
<button type="submit">{% trans "Go" %}</button>

{# Translators: This is a text of the base template #}
{% blocktrans %}Ambiguous translatable block of text{% endblocktrans %}
```

**Note:** Just for completeness, these are the corresponding fragments of the resulting `.po` file:

```
#. Translators: View verb
# path/to/template/file.html:10
msgid "View"
msgstr ""

#. Translators: Short intro blurb
# path/to/template/file.html:13
msgid ""
"A multiline translatable"
"literal."
msgstr ""

# ...

#. Translators: Label of a button that triggers search
# path/to/template/file.html:100
msgid "Go"
msgstr ""

#. Translators: This is a text of the base template
# path/to/template/file.html:103
msgid "Ambiguous translatable block of text"
msgstr ""
```

## Switching language in templates

If you want to select a language within a template, you can use the `language` template tag:

```
{% load i18n %}

{% get_current_language as LANGUAGE_CODE %}
<!-- Current language: {{ LANGUAGE_CODE }} -->
<p>{% trans "Welcome to our page" %}</p>

{% language 'en' %}
    {% get_current_language as LANGUAGE_CODE %}
    <!-- Current language: {{ LANGUAGE_CODE }} -->
    <p>{% trans "Welcome to our page" %}</p>
{% endlanguage %}
```

While the first occurrence of “Welcome to our page” uses the current language, the second will always be in English.

## Other tags

These tags also require a `{% load i18n %}`.

### `get_available_languages`

`{% get_available_languages as LANGUAGES %}` returns a list of tuples in which the first element is the *language code* and the second is the language name (translated into the currently active locale).

### get\_current\_language

`{% get_current_language as LANGUAGE_CODE %}` returns the current user's preferred language as a string. Example: en-us. See *How Django discovers language preference*.

### get\_current\_language\_bidi

`{% get_current_language_bidi as LANGUAGE_BIDI %}` returns the current locale's direction. If True, it's a right-to-left language, e.g. Hebrew, Arabic. If False it's a left-to-right language, e.g. English, French, German, etc.

If you enable the `django.template.context_processors.i18n` context processor then each `RequestContext` will have access to `LANGUAGES`, `LANGUAGE_CODE`, and `LANGUAGE_BIDI` as defined above.

### get\_language\_info

You can also retrieve information about any of the available languages using provided template tags and filters. To get information about a single language, use the `{% get_language_info %}` tag:

```
{% get_language_info for LANGUAGE_CODE as lang %}
{% get_language_info for "pl" as lang %}
```

You can then access the information:

```
Language code: {{ lang.code }}<br />
Name of language: {{ lang.name_local }}<br />
Name in English: {{ lang.name }}<br />
Bi-directional: {{ lang.bidi }}
Name in the active language: {{ lang.name_translated }}
```

The `name_translated` attribute was added.

### get\_language\_info\_list

You can also use the `{% get_language_info_list %}` template tag to retrieve information for a list of languages (e.g. active languages as specified in `LANGUAGES`). See *the section about the set\_language redirect view* for an example of how to display a language selector using `{% get_language_info_list %}`.

In addition to `LANGUAGES` style list of tuples, `{% get_language_info_list %}` supports simple lists of language codes. If you do this in your view:

```
context = {'available_languages': ['en', 'es', 'fr']}
return render(request, 'mytemplate.html', context)
```

you can iterate over those languages in the template:

```
{% get_language_info_list for available_languages as langs %}
{% for lang in langs %} ... {% endfor %}
```

## Template filters

There are also simple filters available for convenience:

- `{{ LANGUAGE_CODE|language_name }}` (“German”)
- `{{ LANGUAGE_CODE|language_name_local }}` (“Deutsch”)
- `{{ LANGUAGE_CODE|language_bidi }}` (False)
- `{{ LANGUAGE_CODE|language_name_translated }}` (“německy”, when active language is Czech)

The `language_name_translated` filter was added.

## Internationalization: in JavaScript code

Adding translations to JavaScript poses some problems:

- JavaScript code doesn’t have access to a `gettext` implementation.
- JavaScript code doesn’t have access to `.po` or `.mo` files; they need to be delivered by the server.
- The translation catalogs for JavaScript should be kept as small as possible.

Django provides an integrated solution for these problems: It passes the translations into JavaScript, so you can call `gettext`, etc., from within JavaScript.

The main solution to these problems is the following `JavaScriptCatalog` view, which generates a JavaScript code library with functions that mimic the `gettext` interface, plus an array of translation strings.

### The `JavaScriptCatalog` view

#### class `JavaScriptCatalog`

A view that produces a JavaScript code library with functions that mimic the `gettext` interface, plus an array of translation strings.

#### Attributes

##### `domain`

Translation domain containing strings to add in the view output. Defaults to `'djangojs'`.

##### `packages`

A list of *application names* among installed applications. Those apps should contain a `locale` directory. All those catalogs plus all catalogs found in `LOCALE_PATHS` (which are always included) are merged into one catalog. Defaults to `None`, which means that all available translations from all `INSTALLED_APPS` are provided in the JavaScript output.

#### Example with default values:

```
from django.views.i18n import JavaScriptCatalog

urlpatterns = [
    url(r'^jsi18n/$', JavaScriptCatalog.as_view(), name='javascript-catalog'),
]
```

#### Example with custom packages:

```
urlpatterns = [
    url(r'^jsi18n/myapp/$',
        JavaScriptCatalog.as_view(packages=['your.app.label']),
        name='javascript-catalog'),
]
```

If your root `URLconf` uses `i18n_patterns()`, `JavaScriptCatalog` must also be wrapped by `i18n_patterns()` for the catalog to be correctly generated.

**Example with `i18n_patterns()`:**

```
from django.conf.urls.i18n import i18n_patterns

urlpatterns = i18n_patterns(
    url(r'^jsi18n/$', JavaScriptCatalog.as_view(), name='javascript-catalog'),
)
```

The precedence of translations is such that the packages appearing later in the `packages` argument have higher precedence than the ones appearing at the beginning. This is important in the case of clashing translations for the same literal.

If you use more than one `JavaScriptCatalog` view on a site and some of them define the same strings, the strings in the catalog that was loaded last take precedence.

### The `javascript_catalog` view

`javascript_catalog` (*request*, *domain*='djangojs', *packages*=None)

Deprecated since version 1.10: `javascript_catalog()` is deprecated in favor of `JavaScriptCatalog` and will be removed in Django 2.0.

The main solution to these problems is the `django.views.i18n.javascript_catalog()` view, which sends out a JavaScript code library with functions that mimic the `gettext` interface, plus an array of translation strings. Those translation strings are taken from applications or Django core, according to what you specify in either the `info_dict` or the URL. Paths listed in `LOCALE_PATHS` are also included.

You hook it up like this:

```
from django.views.i18n import javascript_catalog

js_info_dict = {
    'packages': ('your.app.package',),
}

urlpatterns = [
    url(r'^jsi18n/$', javascript_catalog, js_info_dict, name='javascript-catalog'),
]
```

Each string in `packages` should be in Python dotted-package syntax (the same format as the strings in `INSTALLED_APPS`) and should refer to a package that contains a `locale` directory. If you specify multiple packages, all those catalogs are merged into one catalog. This is useful if you have JavaScript that uses strings from different applications.

The precedence of translations is such that the packages appearing later in the `packages` argument have higher precedence than the ones appearing at the beginning, this is important in the case of clashing translations for the same literal.

By default, the view uses the `djangojs` `gettext` domain. This can be changed by altering the `domain` argument.

You can make the view dynamic by putting the packages into the URL pattern:

```
urlpatterns = [
    url(r'^jsi18n/(?P<packages>\S+)/$', javascript_catalog, name='javascript-catalog
↵'),
]
```

With this, you specify the packages as a list of package names delimited by '+' signs in the URL. This is especially useful if your pages use code from different apps and this changes often and you don't want to pull in one big catalog file. As a security measure, these values can only be either `django.conf` or any package from the `INSTALLED_APPS` setting.

You can also split the catalogs in multiple URLs and load them as you need in your sites:

```
js_info_dict_app = {
    'packages': ('your.app.package',),
}

js_info_dict_other_app = {
    'packages': ('your.other.app.package',),
}

urlpatterns = [
    url(r'^jsi18n/app/$', javascript_catalog, js_info_dict_app),
    url(r'^jsi18n/other_app/$', javascript_catalog, js_info_dict_other_app),
]
```

If you use more than one `javascript_catalog` on a site and some of them define the same strings, the strings in the catalog that was loaded last take precedence.

Before Django 1.9, the catalogs completely overwrote each other and you could only use one at a time.

The JavaScript translations found in the paths listed in the `LOCALE_PATHS` setting are also always included. To keep consistency with the translations lookup order algorithm used for Python and templates, the directories listed in `LOCALE_PATHS` have the highest precedence with the ones appearing first having higher precedence than the ones appearing later.

## Using the JavaScript translation catalog

To use the catalog, just pull in the dynamically generated script like this:

```
<script type="text/javascript" src="{% url 'javascript-catalog' %}"></script>
```

This uses reverse URL lookup to find the URL of the JavaScript catalog view. When the catalog is loaded, your JavaScript code can use the following methods:

- `gettext`
- `gettext`
- `interpolate`
- `get_format`
- `gettext_noop`
- `pgettext`
- `npgettext`
- `pluralidx`

## gettext

The `gettext` function behaves similarly to the standard `gettext` interface within your Python code:

```
document.write(gettext('this is to be translated'));
```

## ngettext

The `ngettext` function provides an interface to pluralize words and phrases:

```
var object_count = 1 // or 0, or 2, or 3, ...
s = ngettext('literal for the singular case',
            'literal for the plural case', object_count);
```

## interpolate

The `interpolate` function supports dynamically populating a format string. The interpolation syntax is borrowed from Python, so the `interpolate` function supports both positional and named interpolation:

- **Positional interpolation:** `obj` contains a JavaScript Array object whose elements values are then sequentially interpolated in their corresponding `fmt` placeholders in the same order they appear. For example:

```
fmts = ngettext('There is %s object. Remaining: %s',
               'There are %s objects. Remaining: %s', 11);
s = interpolate(fmts, [11, 20]);
// s is 'There are 11 objects. Remaining: 20'
```

- **Named interpolation:** This mode is selected by passing the optional boolean `named` parameter as `true`. `obj` contains a JavaScript object or associative array. For example:

```
d = {
  count: 10,
  total: 50
};

fmts = ngettext('Total: %(total)s, there is %(count)s object',
               'there are %(count)s of a total of %(total)s objects', d.count);
s = interpolate(fmts, d, true);
```

You shouldn't go over the top with string interpolation, though: this is still JavaScript, so the code has to make repeated regular-expression substitutions. This isn't as fast as string interpolation in Python, so keep it to those cases where you really need it (for example, in conjunction with `ngettext` to produce proper pluralizations).

## get\_format

The `get_format` function has access to the configured `i18n` formatting settings and can retrieve the format string for a given setting name:

```
document.write(get_format('DATE_FORMAT'));
// 'N j, Y'
```

It has access to the following settings:

- `DATE_FORMAT`
- `DATE_INPUT_FORMATS`
- `DATETIME_FORMAT`
- `DATETIME_INPUT_FORMATS`
- `DECIMAL_SEPARATOR`
- `FIRST_DAY_OF_WEEK`
- `MONTH_DAY_FORMAT`
- `NUMBER_GROUPING`
- `SHORT_DATE_FORMAT`
- `SHORT_DATETIME_FORMAT`
- `THOUSAND_SEPARATOR`
- `TIME_FORMAT`
- `TIME_INPUT_FORMATS`
- `YEAR_MONTH_FORMAT`

This is useful for maintaining formatting consistency with the Python-rendered values.

#### `gettext_noop`

This emulates the `gettext` function but does nothing, returning whatever is passed to it:

```
document.write(gettext_noop('this will not be translated'));
```

This is useful for stubbing out portions of the code that will need translation in the future.

#### `pgettext`

The `pgettext` function behaves like the Python variant (`pgettext()`), providing a contextually translated word:

```
document.write(pgettext('month name', 'May'));
```

#### `npgettext`

The `npgettext` function also behaves like the Python variant (`npgettext()`), providing a **pluralized** contextually translated word:

```
document.write(npgettext('group', 'party', 1));  
// party  
document.write(npgettext('group', 'party', 2));  
// parties
```

## pluralidx

The `pluralidx` function works in a similar way to the `pluralize` template filter, determining if a given count should use a plural form of a word or not:

```
document.write(pluralidx(0));
// true
document.write(pluralidx(1));
// false
document.write(pluralidx(2));
// true
```

In the simplest case, if no custom pluralization is needed, this returns `false` for the integer 1 and `true` for all other numbers.

However, pluralization is not this simple in all languages. If the language does not support pluralization, an empty value is provided.

Additionally, if there are complex rules around pluralization, the catalog view will render a conditional expression. This will evaluate to either a `true` (should pluralize) or `false` (should **not** pluralize) value.

## The JSONCatalog view

### class JSONCatalog

In order to use another client-side library to handle translations, you may want to take advantage of the `JSONCatalog` view. It's similar to `JavaScriptCatalog` but returns a JSON response.

See the documentation for `JavaScriptCatalog` to learn about possible values and use of the `domain` and `packages` attributes.

The response format is as follows:

```
{
  "catalog": {
    # Translations catalog
  },
  "formats": {
    # Language formats for date, time, etc.
  },
  "plural": "... " # Expression for plural forms, or null.
}
```

## The json\_catalog view

`json_catalog(request, domain='djangojs', packages=None)`

Deprecated since version 1.10: `json_catalog()` is deprecated in favor of `JSONCatalog` and will be removed in Django 2.0.

In order to use another client-side library to handle translations, you may want to take advantage of the `json_catalog()` view. It's similar to `javascript_catalog()` but returns a JSON response.

The JSON object contains `i18n` formatting settings (those available for `get_format`), a plural rule (as a `plural` part of a GNU `gettext Plural-Forms` expression), and translation strings. The translation strings are taken from applications or Django's own translations, according to what is specified either via `urlpatterns` arguments or as request parameters. Paths listed in `LOCALE_PATHS` are also included.

The view is hooked up to your application and configured in the same fashion as `javascript_catalog()` (namely, the `domain` and `packages` arguments behave identically):

```
from django.views.i18n import json_catalog

js_info_dict = {
    'packages': ('your.app.package',),
}

urlpatterns = [
    url(r'^jsi18n/$', json_catalog, js_info_dict),
]
```

The response format is as follows:

```
{
  "catalog": {
    # Translations catalog
  },
  "formats": {
    # Language formats for date, time, etc.
  },
  "plural": "..." # Expression for plural forms, or null.
}
```

### Note on performance

The various JavaScript/JSON i18n views generate the catalog from `.mo` files on every request. Since its output is constant, at least for a given version of a site, it's a good candidate for caching.

Server-side caching will reduce CPU load. It's easily implemented with the `cache_page()` decorator. To trigger cache invalidation when your translations change, provide a version-dependent key prefix, as shown in the example below, or map the view at a version-dependent URL:

```
from django.views.decorators.cache import cache_page
from django.views.i18n import JavaScriptCatalog

# The value returned by get_version() must change when translations change.
urlpatterns = [
    url(r'^jsi18n/$',
        cache_page(86400, key_prefix='js18n-%s' % get_version())(JavaScriptCatalog.as_
↪view()),
        name='javascript-catalog'),
]
```

Client-side caching will save bandwidth and make your site load faster. If you're using ETags (`USE_ETAGS = True`), you're already covered. Otherwise, you can apply *conditional decorators*. In the following example, the cache is invalidated whenever you restart your application server:

```
from django.utils import timezone
from django.views.decorators.http import last_modified
from django.views.i18n import JavaScriptCatalog

last_modified_date = timezone.now()

urlpatterns = [
    url(r'^jsi18n/$',
```

```

    last_modified(lambda req, **kw: last_modified_date)(JavaScriptCatalog.as_
↪view()),
    name='javascript-catalog'),
]

```

You can even pre-generate the JavaScript catalog as part of your deployment procedure and serve it as a static file. This radical technique is implemented in `django-statici18n`.

## Internationalization: in URL patterns

Django provides two mechanisms to internationalize URL patterns:

- Adding the language prefix to the root of the URL patterns to make it possible for `LocaleMiddleware` to detect the language to activate from the requested URL.
- Making URL patterns themselves translatable via the `django.utils.translation.ugettext_lazy()` function.

**Warning:** Using either one of these features requires that an active language be set for each request; in other words, you need to have `django.middleware.locale.LocaleMiddleware` in your `MIDDLEWARE` setting.

## Language prefix in URL patterns

`i18n_patterns` (*\*urls, prefix\_default\_language=True*)

This function can be used in a root URLconf and Django will automatically prepend the current active language code to all URL patterns defined within `i18n_patterns()`.

Setting `prefix_default_language` to `False` removes the prefix from the default language (`LANGUAGE_CODE`). This can be useful when adding translations to existing site so that the current URLs won't change.

Example URL patterns:

```

from django.conf.urls import include, url
from django.conf.urls.i18n import i18n_patterns

from about import views as about_views
from news import views as news_views
from sitemap.views import sitemap

urlpatterns = [
    url(r'^sitemap\.xml$', sitemap, name='sitemap-xml'),
]

news_patterns = ([
    url(r'^$', news_views.index, name='index'),
    url(r'^category/(?P<slug>[\w-]+)/$', news_views.category, name='category'),
    url(r'^(?P<slug>[\w-]+)/$', news_views.details, name='detail'),
], 'news')

urlpatterns += i18n_patterns(
    url(r'^about/$', about_views.main, name='about'),

```

```
url(r'^news/', include(news_patterns, namespace='news')),
)
```

After defining these URL patterns, Django will automatically add the language prefix to the URL patterns that were added by the `i18n_patterns` function. Example:

```
>>> from django.urls import reverse
>>> from django.utils.translation import activate

>>> activate('en')
>>> reverse('sitemap-xml')
'/sitemap.xml'
>>> reverse('news:index')
'/en/news/'

>>> activate('nl')
>>> reverse('news:detail', kwargs={'slug': 'news-slug'})
'/nl/news/news-slug/'
```

With `prefix_default_language=False` and `LANGUAGE_CODE='en'`, the URLs will be:

```
>>> activate('en')
>>> reverse('news:index')
'/news/'

>>> activate('nl')
>>> reverse('news:index')
'/nl/news/'
```

The `prefix_default_language` parameter was added.

**Warning:** `i18n_patterns()` is only allowed in a root URLconf. Using it within an included URLconf will throw an `ImproperlyConfigured` exception.

In older version, using `i18n_patterns` in a root URLconf different from `ROOT_URLCONF` by setting `request.urlconf` wasn't supported.

**Warning:** Ensure that you don't have non-prefixed URL patterns that might collide with an automatically-added language prefix.

## Translating URL patterns

URL patterns can also be marked translatable using the `ugettext_lazy()` function. Example:

```
from django.conf.urls import include, url
from django.conf.urls.i18n import i18n_patterns
from django.utils.translation import ugettext_lazy as _

from about import views as about_views
from news import views as news_views
from sitemaps.views import sitemap
```

```
urlpatterns = [
    url(r'^sitemap\.xml$', sitemap, name='sitemap-xml'),
]

news_patterns = ([
    url(r'^$', news_views.index, name='index'),
    url(_(r'^category/(?P<slug>[\w-]+)/$'), news_views.category, name='category'),
    url(r'^(?P<slug>[\w-]+)/$', news_views.details, name='detail'),
], 'news')

urlpatterns += i18n_patterns(
    url(_(r'^about/$'), about_views.main, name='about'),
    url(_(r'^news/'), include(news_patterns, namespace='news')),
)
```

After you've created the translations, the `reverse()` function will return the URL in the active language. Example:

```
>>> from django.urls import reverse
>>> from django.utils.translation import activate

>>> activate('en')
>>> reverse('news:category', kwargs={'slug': 'recent'})
'/en/news/category/recent/'

>>> activate('nl')
>>> reverse('news:category', kwargs={'slug': 'recent'})
'/nl/nieuws/categorie/recent/'
```

**Warning:** In most cases, it's best to use translated URLs only within a language-code-prefixed block of patterns (using `i18n_patterns()`), to avoid the possibility that a carelessly translated URL causes a collision with a non-translated URL pattern.

## Reversing in templates

If localized URLs get reversed in templates they always use the current language. To link to a URL in another language use the `language` template tag. It enables the given language in the enclosed template section:

```
{% load i18n %}

{% get_available_languages as languages %}

{% trans "View this category in:" %}
{% for lang_code, lang_name in languages %}
    {% language lang_code %}
    <a href="{% url 'category' slug=category.slug %}">{{ lang_name }}</a>
    {% endlanguage %}
{% endfor %}
```

The `language` tag expects the language code as the only argument.

## Localization: how to create language files

Once the string literals of an application have been tagged for later translation, the translation themselves need to be written (or obtained). Here's how that works.

### Message files

The first step is to create a *message file* for a new language. A message file is a plain-text file, representing a single language, that contains all available translation strings and how they should be represented in the given language. Message files have a `.po` file extension.

Django comes with a tool, `django-admin makemessages`, that automates the creation and upkeep of these files.

---

### Gettext utilities

The `makemessages` command (and `compilemessages` discussed later) use commands from the GNU gettext toolset: `xgettext`, `msgfmt`, `msgmerge` and `msguniq`.

The minimum version of the `gettext` utilities supported is 0.15.

---

To create or update a message file, run this command:

```
django-admin makemessages -l de
```

...where `de` is the *locale name* for the message file you want to create. For example, `pt_BR` for Brazilian Portuguese, `de_AT` for Austrian German or `id` for Indonesian.

The script should be run from one of two places:

- The root directory of your Django project (the one that contains `manage.py`).
- The root directory of one of your Django apps.

The script runs over your project source tree or your application source tree and pulls out all strings marked for translation (see *How Django discovers translations* and be sure `LOCALE_PATHS` is configured correctly). It creates (or updates) a message file in the directory `locale/LANG/LC_MESSAGES`. In the `de` example, the file will be `locale/de/LC_MESSAGES/django.po`.

When you run `makemessages` from the root directory of your project, the extracted strings will be automatically distributed to the proper message files. That is, a string extracted from a file of an app containing a `locale` directory will go in a message file under that directory. A string extracted from a file of an app without any `locale` directory will either go in a message file under the directory listed first in `LOCALE_PATHS` or will generate an error if `LOCALE_PATHS` is empty.

By default `django-admin makemessages` examines every file that has the `.html` or `.txt` file extension. In case you want to override that default, use the `--extension` or `-e` option to specify the file extensions to examine:

```
django-admin makemessages -l de -e txt
```

Separate multiple extensions with commas and/or use `-e` or `--extension` multiple times:

```
django-admin makemessages -l de -e html,txt -e xml
```

**Warning:** When *creating message files from JavaScript source code* you need to use the special 'djangojs' domain, **not** `-e js`.

### Using Jinja2 templates?

`makemessages` doesn't understand the syntax of Jinja2 templates. To extract strings from a project containing Jinja2 templates, use [Message Extracting](#) from [Babel](#) instead.

Here's an example `babel.cfg` configuration file:

```
# Extraction from Python source files
[python: **.py]

# Extraction from Jinja2 templates
[jinja2: **.jinja]
extensions = jinja2.ext.with_
```

Make sure you list all extensions you're using! Otherwise Babel won't recognize the tags defined by these extensions and will ignore Jinja2 templates containing them entirely.

Babel provides similar features to `makemessages`, can replace it in general, and doesn't depend on `gettext`. For more information, read its documentation about [working with message catalogs](#).

---

### No gettext?

If you don't have the `gettext` utilities installed, `makemessages` will create empty files. If that's the case, either install the `gettext` utilities or just copy the English message file (`locale/en/LC_MESSAGES/django.po`) if available and use it as a starting point; it's just an empty translation file.

---

### Working on Windows?

If you're using Windows and need to install the GNU `gettext` utilities so `makemessages` works, see [gettext on Windows](#) for more information.

---

The format of `.po` files is straightforward. Each `.po` file contains a small bit of metadata, such as the translation maintainer's contact information, but the bulk of the file is a list of **messages** – simple mappings between translation strings and the actual translated text for the particular language.

For example, if your Django app contained a translation string for the text "Welcome to my site.", like so:

```
_("Welcome to my site.")
```

...then `django-admin makemessages` will have created a `.po` file containing the following snippet – a message:

```
#: path/to/python/module.py:23
msgid "Welcome to my site."
msgstr ""
```

A quick explanation:

- `msgid` is the translation string, which appears in the source. Don't change it.
- `msgstr` is where you put the language-specific translation. It starts out empty, so it's your responsibility to change it. Make sure you keep the quotes around your translation.
- As a convenience, each message includes, in the form of a comment line prefixed with `#` and located above the `msgid` line, the filename and line number from which the translation string was gleaned.

Long messages are a special case. There, the first string directly after the `msgstr` (or `msgid`) is an empty string. Then the content itself will be written over the next few lines as one string per line. Those strings are directly concatenated. Don't forget trailing spaces within the strings; otherwise, they'll be tacked together without whitespace!

---

### Mind your charset

Due to the way the `gettext` tools work internally and because we want to allow non-ASCII source strings in Django's core and your applications, you **must** use UTF-8 as the encoding for your PO files (the default when PO files are created). This means that everybody will be using the same encoding, which is important when Django processes the PO files.

---

To reexamine all source code and templates for new translation strings and update all message files for **all** languages, run this:

```
django-admin makemessages -a
```

### Compiling message files

After you create your message file – and each time you make changes to it – you'll need to compile it into a more efficient form, for use by `gettext`. Do this with the `django-admin compilemessages` utility.

This tool runs over all available `.po` files and creates `.mo` files, which are binary files optimized for use by `gettext`. In the same directory from which you ran `django-admin makemessages`, run `django-admin compilemessages` like this:

```
django-admin compilemessages
```

That's it. Your translations are ready for use.

`compilemessages` now matches the operation of `makemessages`, scanning the project tree for `.po` files to compile.

---

### Working on Windows?

If you're using Windows and need to install the GNU `gettext` utilities so `django-admin compilemessages` works see [gettext on Windows](#) for more information.

---

### .po files: Encoding and BOM usage.

Django only supports `.po` files encoded in UTF-8 and without any BOM (Byte Order Mark) so if your text editor adds such marks to the beginning of files by default then you will need to reconfigure it.

---

### Troubleshooting: `ugettext ()` incorrectly detects `python-format` in strings with percent signs

In some cases, such as strings with a percent sign followed by a space and a `string conversion type` (e.g. `_("10% interest")`), `ugettext ()` incorrectly flags strings with `python-format`.

If you try to compile message files with incorrectly flagged strings, you'll get an error message like `number of format specifications in 'msgid' and 'msgstr' does not match or 'msgstr' is not a valid Python format string, unlike 'msgid'`.

To workaroud this, you can escape percent signs by adding a second percent sign:

```
from django.utils.translation import ugettext as _
output = _("10%% interest")
```

Or you can use `no-python-format` so that all percent signs are treated as literals:

```
# xgettext:no-python-format
output = _("10% interest")
```

## Creating message files from JavaScript source code

You create and update the message files the same way as the other Django message files – with the `django-admin makemessages` tool. The only difference is you need to explicitly specify what in gettext parlance is known as a domain in this case the `djangojs` domain, by providing a `-d djangojs` parameter, like this:

```
django-admin makemessages -d djangojs -l de
```

This would create or update the message file for JavaScript for German. After updating message files, just run `django-admin compilemessages` the same way as you do with normal Django message files.

## gettext on Windows

This is only needed for people who either want to extract message IDs or compile message files (`.po`). Translation work itself just involves editing existing files of this type, but if you want to create your own message files, or want to test or compile a changed message file, download [a precompiled binary installer](#).

You may also use `gettext` binaries you have obtained elsewhere, so long as the `xgettext --version` command works properly. Do not attempt to use Django translation utilities with a `gettext` package if the command `xgettext --version` entered at a Windows command prompt causes a popup window saying “`xgettext.exe` has generated errors and will be closed by Windows”.

## Customizing the makemessages command

If you want to pass additional parameters to `xgettext`, you need to create a custom `makemessages` command and override its `xgettext_options` attribute:

```
from django.core.management.commands import makemessages

class Command(makemessages.Command):
    xgettext_options = makemessages.Command.xgettext_options + ['--keyword=mytrans']
```

If you need more flexibility, you could also add a new argument to your custom `makemessages` command:

```
from django.core.management.commands import makemessages

class Command(makemessages.Command):

    def add_arguments(self, parser):
        super(Command, self).add_arguments(parser)
        parser.add_argument(
            '--extra-keyword',
            dest='xgettext_keywords',
            action='append',
        )
```

```
def handle(self, *args, **options):
    xgettext_keywords = options.pop('xgettext_keywords')
    if xgettext_keywords:
        self.xgettext_options = (
            makemessages.Command.xgettext_options[:] +
            ['--keyword=%s' % kwd for kwd in xgettext_keywords]
        )
    super(Command, self).handle(*args, **options)
```

## Miscellaneous

### The `set_language` redirect view

#### `set_language` (*request*)

As a convenience, Django comes with a view, `django.views.i18n.set_language()`, that sets a user's language preference and redirects to a given URL or, by default, back to the previous page.

Activate this view by adding the following line to your URLconf:

```
url(r'^i18n/', include('django.conf.urls.i18n')),
```

(Note that this example makes the view available at `/i18n/setlang/`.)

**Warning:** Make sure that you don't include the above URL within `i18n_patterns()` - it needs to be language-independent itself to work correctly.

The view expects to be called via the POST method, with a `language` parameter set in request. If session support is enabled, the view saves the language choice in the user's session. Otherwise, it saves the language choice in a cookie that is by default named `django_language`. (The name can be changed through the `LANGUAGE_COOKIE_NAME` setting.)

After setting the language choice, Django looks for a `next` parameter in the POST or GET data. If that is found and Django considers it to be a safe URL (i.e. it doesn't point to a different host and uses a safe scheme), a redirect to that URL will be performed. Otherwise, Django may fall back to redirecting the user to the URL from the `Referer` header or, if it is not set, to `/`, depending on the nature of the request:

- For AJAX requests, the fallback will be performed only if the `next` parameter was set. Otherwise a 204 status code (No Content) will be returned.
- For non-AJAX requests, the fallback will always be performed.

Returning a 204 status code for AJAX requests when no redirect is specified is new.

Here's example HTML template code:

```
{% load i18n %}

<form action="{% url 'set_language' %}" method="post">{% csrf_token %}
  <input name="next" type="hidden" value="{{ redirect_to }}" />
  <select name="language">
    {% get_current_language as LANGUAGE_CODE %}
    {% get_available_languages as LANGUAGES %}
    {% get_language_info_list for LANGUAGES as languages %}
    {% for language in languages %}
```

```

        <option value="{{ language.code }}" {% if language.code == LANGUAGE_CODE %}
↪ selected="selected" {% endif %}>
            {{ language.name_local }} ({{ language.code }})
        </option>
    {% endfor %}
</select>
<input type="submit" value="Go" />
</form>

```

In this example, Django looks up the URL of the page to which the user will be redirected in the `redirect_to` context variable.

### Explicitly setting the active language

You may want to set the active language for the current session explicitly. Perhaps a user's language preference is retrieved from another system, for example. You've already been introduced to `django.utils.translation.activate()`. That applies to the current thread only. To persist the language for the entire session, also modify `LANGUAGE_SESSION_KEY` in the session:

```

from django.utils import translation
user_language = 'fr'
translation.activate(user_language)
request.session[translation.LANGUAGE_SESSION_KEY] = user_language

```

You would typically want to use both: `django.utils.translation.activate()` will change the language for this thread, and modifying the session makes this preference persist in future requests.

If you are not using sessions, the language will persist in a cookie, whose name is configured in `LANGUAGE_COOKIE_NAME`. For example:

```

from django.utils import translation
from django import http
from django.conf import settings
user_language = 'fr'
translation.activate(user_language)
response = http.HttpResponse(...)
response.set_cookie(settings.LANGUAGE_COOKIE_NAME, user_language)

```

### Using translations outside views and templates

While Django provides a rich set of i18n tools for use in views and templates, it does not restrict the usage to Django-specific code. The Django translation mechanisms can be used to translate arbitrary texts to any language that is supported by Django (as long as an appropriate translation catalog exists, of course). You can load a translation catalog, activate it and translate text to language of your choice, but remember to switch back to original language, as activating a translation catalog is done on per-thread basis and such change will affect code running in the same thread.

For example:

```

from django.utils import translation

def welcome_translated(language):
    cur_language = translation.get_language()
    try:

```

```
translation.activate(language)
text = translation.ugettext('welcome')
finally:
    translation.activate(cur_language)
return text
```

Calling this function with the value 'de' will give you "Willkommen", regardless of `LANGUAGE_CODE` and language set by middleware.

Functions of particular interest are `django.utils.translation.get_language()` which returns the language used in the current thread, `django.utils.translation.activate()` which activates a translation catalog for the current thread, and `django.utils.translation.check_for_language()` which checks if the given language is supported by Django.

To help write more concise code, there is also a context manager `django.utils.translation.override()` that stores the current language on enter and restores it on exit. With it, the above example becomes:

```
from django.utils import translation

def welcome_translated(language):
    with translation.override(language):
        return translation.ugettext('welcome')
```

## Language cookie

A number of settings can be used to adjust language cookie options:

- `LANGUAGE_COOKIE_NAME`
- `LANGUAGE_COOKIE_AGE`
- `LANGUAGE_COOKIE_DOMAIN`
- `LANGUAGE_COOKIE_PATH`

## Implementation notes

### Specialties of Django translation

Django's translation machinery uses the standard `gettext` module that comes with Python. If you know `gettext`, you might note these specialties in the way Django does translation:

- The string domain is `django` or `djangojs`. This string domain is used to differentiate between different programs that store their data in a common message-file library (usually `/usr/share/locale/`). The `django` domain is used for Python and template translation strings and is loaded into the global translation catalogs. The `djangojs` domain is only used for JavaScript translation catalogs to make sure that those are as small as possible.
- Django doesn't use `xgettext` alone. It uses Python wrappers around `xgettext` and `msgfmt`. This is mostly for convenience.

## How Django discovers language preference

Once you've prepared your translations – or, if you just want to use the translations that come with Django – you'll just need to activate translation for your app.

Behind the scenes, Django has a very flexible model of deciding which language should be used – installation-wide, for a particular user, or both.

To set an installation-wide language preference, set `LANGUAGE_CODE`. Django uses this language as the default translation – the final attempt if no better matching translation is found through one of the methods employed by the locale middleware (see below).

If all you want is to run Django with your native language all you need to do is set `LANGUAGE_CODE` and make sure the corresponding *message files* and their compiled versions (`.mo`) exist.

If you want to let each individual user specify which language they prefer, then you also need to use the `LocaleMiddleware`. `LocaleMiddleware` enables language selection based on data from the request. It customizes content for each user.

To use `LocaleMiddleware`, add `'django.middleware.locale.LocaleMiddleware'` to your `MIDDLEWARE` setting. Because middleware order matters, follow these guidelines:

- Make sure it's one of the first middlewares installed.
- It should come after `SessionMiddleware`, because `LocaleMiddleware` makes use of session data. And it should come before `CommonMiddleware` because `CommonMiddleware` needs an activated language in order to resolve the requested URL.
- If you use `CacheMiddleware`, put `LocaleMiddleware` after it.

For example, your `MIDDLEWARE` might look like this:

```
MIDDLEWARE = [
    'django.contrib.sessions.middleware.SessionMiddleware',
    'django.middleware.locale.LocaleMiddleware',
    'django.middleware.common.CommonMiddleware',
]
```

(For more on middleware, see the [middleware documentation](#).)

`LocaleMiddleware` tries to determine the user's language preference by following this algorithm:

- First, it looks for the language prefix in the requested URL. This is only performed when you are using the `i18n_patterns` function in your root `URLconf`. See *Internationalization: in URL patterns* for more information about the language prefix and how to internationalize URL patterns.
- Failing that, it looks for the `LANGUAGE_SESSION_KEY` key in the current user's session.
- Failing that, it looks for a cookie.
 

The name of the cookie used is set by the `LANGUAGE_COOKIE_NAME` setting. (The default name is `django_language`.)
- Failing that, it looks at the `Accept-Language` HTTP header. This header is sent by your browser and tells the server which language(s) you prefer, in order by priority. Django tries each language in the header until it finds one with available translations.
- Failing that, it uses the global `LANGUAGE_CODE` setting.

Notes:

- In each of these places, the language preference is expected to be in the standard *language format*, as a string. For example, Brazilian Portuguese is `pt-br`.
- If a base language is available but the sublanguage specified is not, Django uses the base language. For example, if a user specifies `de-at` (Austrian German) but Django only has `de` available, Django uses `de`.

- Only languages listed in the `LANGUAGES` setting can be selected. If you want to restrict the language selection to a subset of provided languages (because your application doesn't provide all those languages), set `LANGUAGES` to a list of languages. For example:

```
LANGUAGES = [
    ('de', _('German')),
    ('en', _('English')),
]
```

This example restricts languages that are available for automatic selection to German and English (and any sublanguage, like de-ch or en-us).

- If you define a custom `LANGUAGES` setting, as explained in the previous bullet, you can mark the language names as translation strings – but use `gettext_lazy()` instead of `gettext()` to avoid a circular import.

Here's a sample settings file:

```
from django.utils.translation import gettext_lazy as _

LANGUAGES = [
    ('de', _('German')),
    ('en', _('English')),
]
```

Once `LocaleMiddleware` determines the user's preference, it makes this preference available as `request.LANGUAGE_CODE` for each `HttpRequest`. Feel free to read this value in your view code. Here's a simple example:

```
from django.http import HttpResponse

def hello_world(request, count):
    if request.LANGUAGE_CODE == 'de-at':
        return HttpResponse("You prefer to read Austrian German.")
    else:
        return HttpResponse("You prefer to read another language.")
```

Note that, with static (middleware-less) translation, the language is in `settings.LANGUAGE_CODE`, while with dynamic (middleware) translation, it's in `request.LANGUAGE_CODE`.

## How Django discovers translations

At runtime, Django builds an in-memory unified catalog of literals-translations. To achieve this it looks for translations by following this algorithm regarding the order in which it examines the different file paths to load the compiled *message files* (`.mo`) and the precedence of multiple translations for the same literal:

1. The directories listed in `LOCALE_PATHS` have the highest precedence, with the ones appearing first having higher precedence than the ones appearing later.
2. Then, it looks for and uses if it exists a locale directory in each of the installed apps listed in `INSTALLED_APPS`. The ones appearing first have higher precedence than the ones appearing later.
3. Finally, the Django-provided base translation in `django/conf/locale` is used as a fallback.

### See also:

The translations for literals included in JavaScript assets are looked up following a similar but not identical algorithm. See the [javascript\\_catalog view documentation](#) for more details.

In all cases the name of the directory containing the translation is expected to be named using *locale name* notation. E.g. de, pt\_BR, es\_AR, etc.

This way, you can write applications that include their own translations, and you can override base translations in your project. Or, you can just build a big project out of several apps and put all translations into one big common message file specific to the project you are composing. The choice is yours.

All message file repositories are structured the same way. They are:

- All paths listed in `LOCALE_PATHS` in your settings file are searched for `<language>/LC_MESSAGES/django.(po|mo)`
- `$APPPATH/locale/<language>/LC_MESSAGES/django.(po|mo)`
- `$PYTHONPATH/django/conf/locale/<language>/LC_MESSAGES/django.(po|mo)`

To create message files, you use the `django-admin makemessages` tool. And you use `django-admin compilemessages` to produce the binary `.mo` files that are used by `gettext`.

You can also run `django-admin compilemessages --settings=path.to.settings` to make the compiler process all the directories in your `LOCALE_PATHS` setting.

## Using a non-English base language

Django makes the general assumption that the original strings in a translatable project are written in English. You can choose another language, but you must be aware of certain limitations:

- `gettext` only provides two plural forms for the original messages, so you will also need to provide a translation for the base language to include all plural forms if the plural rules for the base language are different from English.
- When an English variant is activated and English strings are missing, the fallback language will not be the `LANGUAGE_CODE` of the project, but the original strings. For example, an English user visiting a site with Spanish as the default language and original strings written in Russian will fallback to Russian, not to Spanish.

## 3.15.2 Format localization

### Overview

Django's formatting system is capable of displaying dates, times and numbers in templates using the format specified for the current *locale*. It also handles localized input in forms.

When it's enabled, two users accessing the same content may see dates, times and numbers formatted in different ways, depending on the formats for their current locale.

The formatting system is disabled by default. To enable it, it's necessary to set `USE_L10N = True` in your settings file.

---

**Note:** The default `settings.py` file created by `django-admin startproject` includes `USE_L10N = True` for convenience. Note, however, that to enable number formatting with thousand separators it is necessary to set `USE_THOUSAND_SEPARATOR = True` in your settings file. Alternatively, you could use `intcomma` to format numbers in your template.

---

---

**Note:** There is also an independent but related `USE_I18N` setting that controls if Django should activate translation. See *Translation* for more details.

---

## Locale aware input in forms

When formatting is enabled, Django can use localized formats when parsing dates, times and numbers in forms. That means it tries different formats for different locales when guessing the format used by the user when inputting data on forms.

---

**Note:** Django uses different formats for displaying data to those it uses for parsing data. Most notably, the formats for parsing dates can't use the %a (abbreviated weekday name), %A (full weekday name), %b (abbreviated month name), %B (full month name), or %p (AM/PM).

---

To enable a form field to localize input and output data simply use its `localize` argument:

```
class CashRegisterForm(forms.Form):
    product = forms.CharField()
    revenue = forms.DecimalField(max_digits=4, decimal_places=2, localize=True)
```

## Controlling localization in templates

When you have enabled formatting with `USE_L10N`, Django will try to use a locale specific format whenever it outputs a value in a template.

However, it may not always be appropriate to use localized values – for example, if you're outputting JavaScript or XML that is designed to be machine-readable, you will always want unlocalized values. You may also want to use localization in selected templates, rather than using localization everywhere.

To allow for fine control over the use of localization, Django provides the `l10n` template library that contains the following tags and filters.

### Template tags

#### `localize`

Enables or disables localization of template variables in the contained block.

This tag allows a more fine grained control of localization than `USE_L10N`.

To activate or deactivate localization for a template block, use:

```
{% load l10n %}

{% localize on %}
    {{ value }}
{% endlocalize %}

{% localize off %}
    {{ value }}
{% endlocalize %}
```

---

**Note:** The value of `USE_L10N` isn't respected inside of a `{% localize %}` block.

---

See `localize` and `unlocalize` for template filters that will do the same job on a per-variable basis.

## Template filters

### localize

Forces localization of a single value.

For example:

```
{% load l10n %}
{{ value|localize }}
```

To disable localization on a single value, use *unlocalize*. To control localization over a large section of a template, use the *localize* template tag.

### unlocalize

Forces a single value to be printed without localization.

For example:

```
{% load l10n %}
{{ value|unlocalize }}
```

To force localization of a single value, use *localize*. To control localization over a large section of a template, use the *localize* template tag.

## Creating custom format files

Django provides format definitions for many locales, but sometimes you might want to create your own, because a format file doesn't exist for your locale, or because you want to overwrite some of the values.

To use custom formats, specify the path where you'll place format files first. To do that, just set your *FORMAT\_MODULE\_PATH* setting to the package where format files will exist, for instance:

```
FORMAT_MODULE_PATH = [
    'mysite.formats',
    'some_app.formats',
]
```

Files are not placed directly in this directory, but in a directory named as the locale, and must be named *formats.py*. Be careful not to put sensitive information in these files as values inside can be exposed if you pass the string to `django.utils.formats.get_format()` (used by the *date* template filter).

To customize the English formats, a structure like this would be needed:

```
mysite/
  formats/
    __init__.py
  en/
    __init__.py
    formats.py
```

where *formats.py* contains custom format definitions. For example:

```
from __future__ import unicode_literals

THOUSAND_SEPARATOR = '\xa0'
```

to use a non-breaking space (Unicode 00A0) as a thousand separator, instead of the default for English, a comma.

### Limitations of the provided locale formats

Some locales use context-sensitive formats for numbers, which Django's localization system cannot handle automatically.

#### Switzerland (German)

The Swiss number formatting depends on the type of number that is being formatted. For monetary values, a comma is used as the thousand separator and a decimal point for the decimal separator. For all other numbers, a comma is used as decimal separator and a space as thousand separator. The locale format provided by Django uses the generic separators, a comma for decimal and a space for thousand separators.

## 3.15.3 Time zones

### Overview

When support for time zones is enabled, Django stores datetime information in UTC in the database, uses time-zone-aware datetime objects internally, and translates them to the end user's time zone in templates and forms.

This is handy if your users live in more than one time zone and you want to display datetime information according to each user's wall clock.

Even if your website is available in only one time zone, it's still good practice to store data in UTC in your database. The main reason is Daylight Saving Time (DST). Many countries have a system of DST, where clocks are moved forward in spring and backward in autumn. If you're working in local time, you're likely to encounter errors twice a year, when the transitions happen. (The [pytz](#) documentation discusses [these issues](#) in greater detail.) This probably doesn't matter for your blog, but it's a problem if you over-bill or under-bill your customers by one hour, twice a year, every year. The solution to this problem is to use UTC in the code and use local time only when interacting with end users.

Time zone support is disabled by default. To enable it, set `USE_TZ = True` in your settings file. Installing [pytz](#) is highly recommended, but may not be mandatory depending on your particular database backend, operating system and time zone. If you encounter an exception querying dates or times, please try installing it before filing a bug. It's as simple as:

```
$ pip install pytz
```

---

**Note:** The default `settings.py` file created by `django-admin startproject` includes `USE_TZ = True` for convenience.

---

**Note:** There is also an independent but related `USE_L10N` setting that controls whether Django should activate format localization. See [Format localization](#) for more details.

---

If you're wrestling with a particular problem, start with the [time zone FAQ](#).

## Concepts

### Naive and aware datetime objects

Python's `datetime.datetime` objects have a `tzinfo` attribute that can be used to store time zone information, represented as an instance of a subclass of `datetime.tzinfo`. When this attribute is set and describes an offset, a datetime object is **aware**. Otherwise, it's **naive**.

You can use `is_aware()` and `is_naive()` to determine whether datetimes are aware or naive.

When time zone support is disabled, Django uses naive datetime objects in local time. This is simple and sufficient for many use cases. In this mode, to obtain the current time, you would write:

```
import datetime

now = datetime.datetime.now()
```

When time zone support is enabled (`USE_TZ=True`), Django uses time-zone-aware datetime objects. If your code creates datetime objects, they should be aware too. In this mode, the example above becomes:

```
from django.utils import timezone

now = timezone.now()
```

**Warning:** Dealing with aware datetime objects isn't always intuitive. For instance, the `tzinfo` argument of the standard datetime constructor doesn't work reliably for time zones with DST. Using UTC is generally safe; if you're using other time zones, you should review the `pytz` documentation carefully.

**Note:** Python's `datetime.time` objects also feature a `tzinfo` attribute, and PostgreSQL has a matching `time with time zone` type. However, as PostgreSQL's docs put it, this type "exhibits properties which lead to questionable usefulness".

Django only supports naive time objects and will raise an exception if you attempt to save an aware time object, as a `timezone` for a time with no associated date does not make sense.

### Interpretation of naive datetime objects

When `USE_TZ` is `True`, Django still accepts naive datetime objects, in order to preserve backwards-compatibility. When the database layer receives one, it attempts to make it aware by interpreting it in the *default time zone* and raises a warning.

Unfortunately, during DST transitions, some datetimes don't exist or are ambiguous. In such situations, `pytz` raises an exception. Other `tzinfo` implementations, such as the local time zone used as a fallback when `pytz` isn't installed, may raise an exception or return inaccurate results. That's why you should always create aware datetime objects when time zone support is enabled.

In practice, this is rarely an issue. Django gives you aware datetime objects in the models and forms, and most often, new datetime objects are created from existing ones through `timedelta` arithmetic. The only datetime that's often created in application code is the current time, and `timezone.now()` automatically does the right thing.

## Default time zone and current time zone

The **default time zone** is the time zone defined by the `TIME_ZONE` setting.

The **current time zone** is the time zone that's used for rendering.

You should set the current time zone to the end user's actual time zone with `activate()`. Otherwise, the default time zone is used.

---

**Note:** As explained in the documentation of `TIME_ZONE`, Django sets environment variables so that its process runs in the default time zone. This happens regardless of the value of `USE_TZ` and of the current time zone.

When `USE_TZ` is `True`, this is useful to preserve backwards-compatibility with applications that still rely on local time. However, *as explained above*, this isn't entirely reliable, and you should always work with aware datetimes in UTC in your own code. For instance, use `fromtimestamp()` and set the `tz` parameter to `utc`.

---

## Selecting the current time zone

The current time zone is the equivalent of the current *locale* for translations. However, there's no equivalent of the `Accept-Language` HTTP header that Django could use to determine the user's time zone automatically. Instead, Django provides *time zone selection functions*. Use them to build the time zone selection logic that makes sense for you.

Most websites that care about time zones just ask users in which time zone they live and store this information in the user's profile. For anonymous users, they use the time zone of their primary audience or UTC. `pytz` provides *helpers*, like a list of time zones per country, that you can use to pre-select the most likely choices.

Here's an example that stores the current timezone in the session. (It skips error handling entirely for the sake of simplicity.)

Add the following middleware to `MIDDLEWARE`:

```
import pytz

from django.utils import timezone
from django.utils.deprecation import MiddlewareMixin

class TimezoneMiddleware(MiddlewareMixin):
    def process_request(self, request):
        tzname = request.session.get('django_timezone')
        if tzname:
            timezone.activate(pytz.timezone(tzname))
        else:
            timezone.deactivate()
```

Create a view that can set the current timezone:

```
from django.shortcuts import redirect, render

def set_timezone(request):
    if request.method == 'POST':
        request.session['django_timezone'] = request.POST['timezone']
        return redirect('/')
    else:
        return render(request, 'template.html', {'timezones': pytz.common_timezones})
```

Include a form in `template.html` that will POST to this view:

```
{% load tz %}
{% get_current_timezone as TIME_ZONE %}
<form action="{% url 'set_timezone' %}" method="POST">
  {% csrf_token %}
  <label for="timezone">Time zone:</label>
  <select name="timezone">
    {% for tz in timezones %}
      <option value="{{ tz }}" {% if tz == TIME_ZONE %} selected="selected" {% endif
↵>{{ tz }}</option>
    {% endfor %}
  </select>
  <input type="submit" value="Set" />
</form>
```

### Time zone aware input in forms

When you enable time zone support, Django interprets datetimes entered in forms in the *current time zone* and returns aware datetime objects in `cleaned_data`.

If the current time zone raises an exception for datetimes that don't exist or are ambiguous because they fall in a DST transition (the timezones provided by `pytz` do this), such datetimes will be reported as invalid values.

### Time zone aware output in templates

When you enable time zone support, Django converts aware datetime objects to the *current time zone* when they're rendered in templates. This behaves very much like *format localization*.

**Warning:** Django doesn't convert naive datetime objects, because they could be ambiguous, and because your code should never produce naive datetimes when time zone support is enabled. However, you can force conversion with the template filters described below.

Conversion to local time isn't always appropriate – you may be generating output for computers rather than for humans. The following filters and tags, provided by the `tz` template tag library, allow you to control the time zone conversions.

### Template tags

#### `localtime`

Enables or disables conversion of aware datetime objects to the current time zone in the contained block.

This tag has exactly the same effects as the `USE_TZ` setting as far as the template engine is concerned. It allows a more fine grained control of conversion.

To activate or deactivate conversion for a template block, use:

```
{% load tz %}

{% localtime on %}
  {{ value }}
{% endlocaltime %}
```

```
{% localtime off %}
    {{ value }}
{% endlocaltime %}
```

---

**Note:** The value of `USE_TZ` isn't respected inside of a `{% localtime %}` block.

---

## timezone

Sets or unsets the current time zone in the contained block. When the current time zone is unset, the default time zone applies.

```
{% load tz %}

{% timezone "Europe/Paris" %}
    Paris time: {{ value }}
{% endtimezone %}

{% timezone None %}
    Server time: {{ value }}
{% endtimezone %}
```

## get\_current\_timezone

You can get the name of the current time zone using the `get_current_timezone` tag:

```
{% get_current_timezone as TIME_ZONE %}
```

Alternatively, you can activate the `tz()` context processor and use the `TIME_ZONE` context variable.

## Template filters

These filters accept both aware and naive datetimes. For conversion purposes, they assume that naive datetimes are in the default time zone. They always return aware datetimes.

### localtime

Forces conversion of a single value to the current time zone.

For example:

```
{% load tz %}

{{ value|localtime }}
```

### utc

Forces conversion of a single value to UTC.

For example:

```
{% load tz %}
{{ value|utc }}
```

### timezone

Forces conversion of a single value to an arbitrary timezone.

The argument must be an instance of a `tzinfo` subclass or a time zone name. If it is a time zone name, `pytz` is required.

For example:

```
{% load tz %}
{{ value|timezone:"Europe/Paris" }}
```

## Migration guide

Here's how to migrate a project that was started before Django supported time zones.

### Database

#### PostgreSQL

The PostgreSQL backend stores datetimes as `timestamp with time zone`. In practice, this means it converts datetimes from the connection's time zone to UTC on storage, and from UTC to the connection's time zone on retrieval.

As a consequence, if you're using PostgreSQL, you can switch between `USE_TZ = False` and `USE_TZ = True` freely. The database connection's time zone will be set to `TIME_ZONE` or UTC respectively, so that Django obtains correct datetimes in all cases. You don't need to perform any data conversions.

#### Other databases

Other backends store datetimes without time zone information. If you switch from `USE_TZ = False` to `USE_TZ = True`, you must convert your data from local time to UTC – which isn't deterministic if your local time has DST.

### Code

The first step is to add `USE_TZ = True` to your settings file and install `pytz` (if possible). At this point, things should mostly work. If you create naive datetime objects in your code, Django makes them aware when necessary.

However, these conversions may fail around DST transitions, which means you aren't getting the full benefits of time zone support yet. Also, you're likely to run into a few problems because it's impossible to compare a naive datetime with an aware datetime. Since Django now gives you aware datetimes, you'll get exceptions wherever you compare a datetime that comes from a model or a form with a naive datetime that you've created in your code.

So the second step is to refactor your code wherever you instantiate datetime objects to make them aware. This can be done incrementally. `django.utils.timezone` defines some handy helpers for compatibility code: `now()`, `is_aware()`, `is_naive()`, `make_aware()`, and `make_naive()`.

Finally, in order to help you locate code that needs upgrading, Django raises a warning when you attempt to save a naive datetime to the database:

```
RuntimeWarning: DateTimeField modelName.field_name received a naive
datetime (2012-01-01 00:00:00) while time zone support is active.
```

During development, you can turn such warnings into exceptions and get a traceback by adding the following to your settings file:

```
import warnings
warnings.filterwarnings(
    'error', r"DateTimeField .* received a naive datetime",
    RuntimeWarning, r'django\.db\.models\.fields',
)
```

## Fixtures

When serializing an aware datetime, the UTC offset is included, like this:

```
"2011-09-01T13:20:30+03:00"
```

For a naive datetime, it obviously isn't:

```
"2011-09-01T13:20:30"
```

For models with *DateTimeFields*, this difference makes it impossible to write a fixture that works both with and without time zone support.

Fixtures generated with `USE_TZ = False`, or before Django 1.4, use the “naive” format. If your project contains such fixtures, after you enable time zone support, you'll see `RuntimeWarnings` when you load them. To get rid of the warnings, you must convert your fixtures to the “aware” format.

You can regenerate fixtures with `loaddata` then `dumppdata`. Or, if they're small enough, you can simply edit them to add the UTC offset that matches your `TIME_ZONE` to each serialized datetime.

## FAQ

### Setup

#### 1. I don't need multiple time zones. Should I enable time zone support?

Yes. When time zone support is enabled, Django uses a more accurate model of local time. This shields you from subtle and unreproducible bugs around Daylight Saving Time (DST) transitions.

In this regard, time zones are comparable to `unicode` in Python. At first it's hard. You get encoding and decoding errors. Then you learn the rules. And some problems disappear – you never get mangled output again when your application receives non-ASCII input.

When you enable time zone support, you'll encounter some errors because you're using naive datetimes where Django expects aware datetimes. Such errors show up when running tests and they're easy to fix. You'll quickly learn how to avoid invalid operations.

On the other hand, bugs caused by the lack of time zone support are much harder to prevent, diagnose and fix. Anything that involves scheduled tasks or datetime arithmetic is a candidate for subtle bugs that will bite you only once or twice a year.

For these reasons, time zone support is enabled by default in new projects, and you should keep it unless you have a very good reason not to.

## 2. I've enabled time zone support. Am I safe?

Maybe. You're better protected from DST-related bugs, but you can still shoot yourself in the foot by carelessly turning naive datetimes into aware datetimes, and vice-versa.

If your application connects to other systems – for instance, if it queries a Web service – make sure datetimes are properly specified. To transmit datetimes safely, their representation should include the UTC offset, or their values should be in UTC (or both!).

Finally, our calendar system contains interesting traps for computers:

```
>>> import datetime
>>> def one_year_before(value):          # DON'T DO THAT!
...     return value.replace(year=value.year - 1)
>>> one_year_before(datetime.datetime(2012, 3, 1, 10, 0))
datetime.datetime(2011, 3, 1, 10, 0)
>>> one_year_before(datetime.datetime(2012, 2, 29, 10, 0))
Traceback (most recent call last):
...
ValueError: day is out of range for month
```

(To implement this function, you must decide whether 2012-02-29 minus one year is 2011-02-28 or 2011-03-01, which depends on your business requirements.)

## 3. Should I install pytz?

Yes. Django has a policy of not requiring external dependencies, and for this reason `pytz` is optional. However, it's much safer to install it.

As soon as you activate time zone support, Django needs a definition of the default time zone. When `pytz` is available, Django loads this definition from the `tz database`. This is the most accurate solution. Otherwise, it relies on the difference between local time and UTC, as reported by the operating system, to compute conversions. This is less reliable, especially around DST transitions.

Furthermore, if you want to support users in more than one time zone, `pytz` is the reference for time zone definitions.

## 4. How do I interact with a database that stores datetimes in local time?

Set the `TIME_ZONE` option to the appropriate time zone for this database in the `DATABASES` setting.

This is useful for connecting to a database that doesn't support time zones and that isn't managed by Django when `USE_TZ` is `True`.

## Troubleshooting

### 1. My application crashes with `TypeError: can't compare offset-naive and offset-aware datetimes – what's wrong?`

Let's reproduce this error by comparing a naive and an aware datetime:

```
>>> import datetime
>>> from django.utils import timezone
>>> naive = datetime.datetime.utcnow()
>>> aware = timezone.now()
>>> naive == aware
Traceback (most recent call last):
```

```
...
TypeError: can't compare offset-naive and offset-aware datetimes
```

If you encounter this error, most likely your code is comparing these two things:

- a datetime provided by Django – for instance, a value read from a form or a model field. Since you enabled time zone support, it's aware.
- a datetime generated by your code, which is naive (or you wouldn't be reading this).

Generally, the correct solution is to change your code to use an aware datetime instead.

If you're writing a pluggable application that's expected to work independently of the value of `USE_TZ`, you may find `django.utils.timezone.now()` useful. This function returns the current date and time as a naive datetime when `USE_TZ = False` and as an aware datetime when `USE_TZ = True`. You can add or subtract `datetime.timedelta` as needed.

2. **I see lots of** `RuntimeWarning: DateTimeField received a naive datetime (YYYY-MM-DD HH:MM:SS) while time zone support is active – is that bad?`

When time zone support is enabled, the database layer expects to receive only aware datetimes from your code. This warning occurs when it receives a naive datetime. This indicates that you haven't finished porting your code for time zone support. Please refer to the [migration guide](#) for tips on this process.

In the meantime, for backwards compatibility, the datetime is considered to be in the default time zone, which is generally what you expect.

3. `now.date()` **is yesterday! (or tomorrow)**

If you've always used naive datetimes, you probably believe that you can convert a datetime to a date by calling its `date()` method. You also consider that a `date` is a lot like a `datetime`, except that it's less accurate.

None of this is true in a time zone aware environment:

```
>>> import datetime
>>> import pytz
>>> paris_tz = pytz.timezone("Europe/Paris")
>>> new_york_tz = pytz.timezone("America/New_York")
>>> paris = paris_tz.localize(datetime.datetime(2012, 3, 3, 1, 30))
# This is the correct way to convert between time zones with pytz.
>>> new_york = new_york_tz.normalize(paris.astimezone(new_york_tz))
>>> paris == new_york, paris.date() == new_york.date()
(True, False)
>>> paris - new_york, paris.date() - new_york.date()
(datetime.timedelta(0), datetime.timedelta(1))
>>> paris
datetime.datetime(2012, 3, 3, 1, 30, tzinfo=<DstTzInfo 'Europe/Paris' CET+1:00:00_
↳STD>)
>>> new_york
datetime.datetime(2012, 3, 2, 19, 30, tzinfo=<DstTzInfo 'America/New_York' EST-1_
↳day, 19:00:00 STD>)
```

As this example shows, the same datetime has a different date, depending on the time zone in which it is represented. But the real problem is more fundamental.

A datetime represents a **point in time**. It's absolute: it doesn't depend on anything. On the contrary, a date is a **calendar concept**. It's a period of time whose bounds depend on the time zone in which the date is considered. As you can see, these two concepts are fundamentally different, and converting a datetime to a date isn't a deterministic operation.

What does this mean in practice?

Generally, you should avoid converting a `datetime` to `date`. For instance, you can use the `date` template filter to only show the date part of a datetime. This filter will convert the datetime into the current time zone before formatting it, ensuring the results appear correctly.

If you really need to do the conversion yourself, you must ensure the datetime is converted to the appropriate time zone first. Usually, this will be the current timezone:

```
>>> from django.utils import timezone
>>> timezone.activate(pytz.timezone("Asia/Singapore"))
# For this example, we just set the time zone to Singapore, but here's how
# you would obtain the current time zone in the general case.
>>> current_tz = timezone.get_current_timezone()
# Again, this is the correct way to convert between time zones with pytz.
>>> local = current_tz.normalize(Paris.astimezone(current_tz))
>>> local
datetime.datetime(2012, 3, 3, 8, 30, tzinfo=<DstTzInfo 'Asia/Singapore'
↳SGT+8:00:00 STD>)
```

#### 4. I get an error “Are time zone definitions for your database and pytz installed?” pytz is installed, so I guess the problem is my database?

If you are using MySQL, see the *Time zone definitions* section of the MySQL notes for instructions on loading time zone definitions.

## Usage

#### 1. I have a string "2012-02-21 10:28:45" and I know it's in the "Europe/Helsinki" time zone. How do I turn that into an aware datetime?

This is exactly what `pytz` is for.

```
>>> from django.utils.dateparse import parse_datetime
>>> naive = parse_datetime("2012-02-21 10:28:45")
>>> import pytz
>>> pytz.timezone("Europe/Helsinki").localize(naive, is_dst=None)
datetime.datetime(2012, 2, 21, 10, 28, 45, tzinfo=<DstTzInfo 'Europe/Helsinki'
↳EET+2:00:00 STD>)
```

Note that `localize` is a `pytz` extension to the `tzinfo` API. Also, you may want to catch `pytz.InvalidTimeError`. The documentation of `pytz` contains [more examples](#). You should review it before attempting to manipulate aware datetimes.

#### 2. How can I obtain the local time in the current time zone?

Well, the first question is, do you really need to?

You should only use local time when you're interacting with humans, and the template layer provides *filters and tags* to convert datetimes to the time zone of your choice.

Furthermore, Python knows how to compare aware datetimes, taking into account UTC offsets when necessary. It's much easier (and possibly faster) to write all your model and view code in UTC. So, in most circumstances, the datetime in UTC returned by `django.utils.timezone.now()` will be sufficient.

For the sake of completeness, though, if you really want the local time in the current time zone, here's how you can obtain it:

```
>>> from django.utils import timezone
>>> timezone.localtime(timezone.now())
datetime.datetime(2012, 3, 3, 20, 10, 53, 873365, tzinfo=<DstTzInfo 'Europe/Paris
↪' CET+1:00:00 STD>)
```

In this example, `pytz` is installed and the current time zone is "Europe/Paris".

### 3. How can I see all available time zones?

`pytz` provides [helpers](#), including a list of current time zones and a list of all available time zones – some of which are only of historical interest.

## 3.15.4 Overview

The goal of internationalization and localization is to allow a single Web application to offer its content in languages and formats tailored to the audience.

Django has full support for *translation of text, formatting of dates, times and numbers*, and *time zones*.

Essentially, Django does two things:

- It allows developers and template authors to specify which parts of their apps should be translated or formatted for local languages and cultures.
- It uses these hooks to localize Web apps for particular users according to their preferences.

Obviously, translation depends on the target language, and formatting usually depends on the target country. This information is provided by browsers in the `Accept-Language` header. However, the time zone isn't readily available.

## 3.15.5 Definitions

The words “internationalization” and “localization” often cause confusion; here's a simplified definition:

**internationalization** Preparing the software for localization. Usually done by developers.

**localization** Writing the translations and local formats. Usually done by translators.

More details can be found in the [W3C Web Internationalization FAQ](#), the [Wikipedia article](#) or the [GNU gettext documentation](#).

**Warning:** Translation and formatting are controlled by `USE_I18N` and `USE_L10N` settings respectively. However, both features involve internationalization and localization. The names of the settings are an unfortunate result of Django's history.

Here are some other terms that will help us to handle a common language:

**locale name** A locale name, either a language specification of the form `ll` or a combined language and country specification of the form `ll_CC`. Examples: `it`, `de_AT`, `es`, `pt_BR`. The language part is always in lower case and the country part in upper case. The separator is an underscore.

**language code** Represents the name of a language. Browsers send the names of the languages they accept in the `Accept-Language` HTTP header using this format. Examples: `it`, `de-at`, `es`, `pt-br`. Language codes are generally represented in lower-case, but the HTTP `Accept-Language` header is case-insensitive. The separator is a dash.

**message file** A message file is a plain-text file, representing a single language, that contains all available *translation strings* and how they should be represented in the given language. Message files have a `.po` file extension.

**translation string** A literal that can be translated.

**format file** A format file is a Python module that defines the data formats for a given locale.

## 3.16 Logging

### 3.16.1 A quick logging primer

Django uses Python's builtin `logging` module to perform system logging. The usage of this module is discussed in detail in Python's own documentation. However, if you've never used Python's logging framework (or even if you have), here's a quick primer.

#### The cast of players

A Python logging configuration consists of four parts:

- *Loggers*
- *Handlers*
- *Filters*
- *Formatters*

#### Loggers

A logger is the entry point into the logging system. Each logger is a named bucket to which messages can be written for processing.

A logger is configured to have a *log level*. This log level describes the severity of the messages that the logger will handle. Python defines the following log levels:

- **DEBUG**: Low level system information for debugging purposes
- **INFO**: General system information
- **WARNING**: Information describing a minor problem that has occurred.
- **ERROR**: Information describing a major problem that has occurred.
- **CRITICAL**: Information describing a critical problem that has occurred.

Each message that is written to the logger is a *Log Record*. Each log record also has a *log level* indicating the severity of that specific message. A log record can also contain useful metadata that describes the event that is being logged. This can include details such as a stack trace or an error code.

When a message is given to the logger, the log level of the message is compared to the log level of the logger. If the log level of the message meets or exceeds the log level of the logger itself, the message will undergo further processing. If it doesn't, the message will be ignored.

Once a logger has determined that a message needs to be processed, it is passed to a *Handler*.

## Handlers

The handler is the engine that determines what happens to each message in a logger. It describes a particular logging behavior, such as writing a message to the screen, to a file, or to a network socket.

Like loggers, handlers also have a log level. If the log level of a log record doesn't meet or exceed the level of the handler, the handler will ignore the message.

A logger can have multiple handlers, and each handler can have a different log level. In this way, it is possible to provide different forms of notification depending on the importance of a message. For example, you could install one handler that forwards `ERROR` and `CRITICAL` messages to a paging service, while a second handler logs all messages (including `ERROR` and `CRITICAL` messages) to a file for later analysis.

## Filters

A filter is used to provide additional control over which log records are passed from logger to handler.

By default, any log message that meets log level requirements will be handled. However, by installing a filter, you can place additional criteria on the logging process. For example, you could install a filter that only allows `ERROR` messages from a particular source to be emitted.

Filters can also be used to modify the logging record prior to being emitted. For example, you could write a filter that downgrades `ERROR` log records to `WARNING` records if a particular set of criteria are met.

Filters can be installed on loggers or on handlers; multiple filters can be used in a chain to perform multiple filtering actions.

## Formatters

Ultimately, a log record needs to be rendered as text. Formatters describe the exact format of that text. A formatter usually consists of a Python formatting string containing `LogRecord` attributes; however, you can also write custom formatters to implement specific formatting behavior.

### 3.16.2 Using logging

Once you have configured your loggers, handlers, filters and formatters, you need to place logging calls into your code. Using the logging framework is very simple. Here's an example:

```
# import the logging library
import logging

# Get an instance of a logger
logger = logging.getLogger(__name__)

def my_view(request, arg1, arg):
    ...
    if bad_mojo:
        # Log an error message
        logger.error('Something went wrong!')
```

And that's it! Every time the `bad_mojo` condition is activated, an error log record will be written.

## Naming loggers

The call to `logging.getLogger()` obtains (creating, if necessary) an instance of a logger. The logger instance is identified by a name. This name is used to identify the logger for configuration purposes.

By convention, the logger name is usually `__name__`, the name of the python module that contains the logger. This allows you to filter and handle logging calls on a per-module basis. However, if you have some other way of organizing your logging messages, you can provide any dot-separated name to identify your logger:

```
# Get an instance of a specific named logger
logger = logging.getLogger('project.interesting.stuff')
```

The dotted paths of logger names define a hierarchy. The `project.interesting` logger is considered to be a parent of the `project.interesting.stuff` logger; the `project` logger is a parent of the `project.interesting` logger.

Why is the hierarchy important? Well, because loggers can be set to *propagate* their logging calls to their parents. In this way, you can define a single set of handlers at the root of a logger tree, and capture all logging calls in the subtree of loggers. A logging handler defined in the `project` namespace will catch all logging messages issued on the `project.interesting` and `project.interesting.stuff` loggers.

This propagation can be controlled on a per-logger basis. If you don't want a particular logger to propagate to its parents, you can turn off this behavior.

## Making logging calls

The logger instance contains an entry method for each of the default log levels:

- `logger.debug()`
- `logger.info()`
- `logger.warning()`
- `logger.error()`
- `logger.critical()`

There are two other logging calls available:

- `logger.log()`: Manually emits a logging message with a specific log level.
- `logger.exception()`: Creates an `ERROR` level logging message wrapping the current exception stack frame.

### 3.16.3 Configuring logging

Of course, it isn't enough to just put logging calls into your code. You also need to configure the loggers, handlers, filters and formatters to ensure that logging output is output in a useful way.

Python's logging library provides several techniques to configure logging, ranging from a programmatic interface to configuration files. By default, Django uses the `dictConfig` format.

In order to configure logging, you use `LOGGING` to define a dictionary of logging settings. These settings describes the loggers, handlers, filters and formatters that you want in your logging setup, and the log levels and other properties that you want those components to have.

By default, the `LOGGING` setting is merged with *Django's default logging configuration* using the following scheme.

If the `disable_existing_loggers` key in the `LOGGING` dictConfig is set to `True` (which is the default) then all loggers from the default configuration will be disabled. Disabled loggers are not the same as removed; the logger will still exist, but will silently discard anything logged to it, not even propagating entries to a parent logger. Thus you should be very careful using `'disable_existing_loggers': True`; it's probably not what you want. Instead, you can set `disable_existing_loggers` to `False` and redefine some or all of the default loggers; or you can set `LOGGING_CONFIG` to `None` and *handle logging config yourself*.

Logging is configured as part of the general Django `setup()` function. Therefore, you can be certain that loggers are always ready for use in your project code.

## Examples

The full documentation for `dictConfig` format is the best source of information about logging configuration dictionaries. However, to give you a taste of what is possible, here are several examples.

First, here's a simple configuration which writes all logging from the `django` logger to a local file:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'handlers': {
        'file': {
            'level': 'DEBUG',
            'class': 'logging.FileHandler',
            'filename': '/path/to/django/debug.log',
        },
    },
    'loggers': {
        'django': {
            'handlers': ['file'],
            'level': 'DEBUG',
            'propagate': True,
        },
    },
}
```

If you use this example, be sure to change the `'filename'` path to a location that's writable by the user that's running the Django application.

Second, here's an example of how to make the logging system print Django's logging to the console. It may be useful during local development.

By default, this config only sends messages of level `INFO` or higher to the console (same as Django's default logging config, except that the default only displays log records when `DEBUG=True`). Django does not log many such messages. With this config, however, you can also set the environment variable `DJANGO_LOG_LEVEL=DEBUG` to see all of Django's debug logging which is very verbose as it includes all database queries:

```
import os

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
        },
    },
    'loggers': {
```

```

    'django': {
        'handlers': ['console'],
        'level': os.getenv('DJANGO_LOG_LEVEL', 'INFO'),
    },
},
}

```

Django's default logging configuration changed. See [the release notes](#) for a description of the changes.

Finally, here's an example of a fairly complex logging setup:

```

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'verbose': {
            'format': '%(levelname)s %(asctime)s %(module)s %(process)d %(thread)d
↪%(message)s'
        },
        'simple': {
            'format': '%(levelname)s %(message)s'
        },
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        },
        'require_debug_true': {
            '()': 'django.utils.log.RequireDebugTrue',
        },
    },
    'handlers': {
        'console': {
            'level': 'INFO',
            'filters': ['require_debug_true'],
            'class': 'logging.StreamHandler',
            'formatter': 'simple'
        },
        'mail_admins': {
            'level': 'ERROR',
            'class': 'django.utils.log.AdminEmailHandler',
            'filters': ['special']
        }
    },
    'loggers': {
        'django': {
            'handlers': ['console'],
            'propagate': True,
        },
        'django.request': {
            'handlers': ['mail_admins'],
            'level': 'ERROR',
            'propagate': False,
        },
        'myproject.custom': {
            'handlers': ['console', 'mail_admins'],
            'level': 'INFO',
        }
    }
}

```

```
        'filters': ['special']
    }
}
```

This logging configuration does the following things:

- Identifies the configuration as being in ‘dictConfig version 1’ format. At present, this is the only dictConfig format version.
- Defines two formatters:
  - `simple`, that just outputs the log level name (e.g., `DEBUG`) and the log message.  
The `format` string is a normal Python formatting string describing the details that are to be output on each logging line. The full list of detail that can be output can be found in [Formatter Objects](#).
  - `verbose`, that outputs the log level name, the log message, plus the time, process, thread and module that generate the log message.
- Defines two filters:
  - `project.logging.SpecialFilter`, using the alias `special`. If this filter required additional arguments, they can be provided as additional keys in the filter configuration dictionary. In this case, the argument `foo` will be given a value of `bar` when instantiating `SpecialFilter`.
  - `django.utils.log.RequireDebugTrue`, which passes on records when `DEBUG` is `True`.
- Defines two handlers:
  - `console`, a `StreamHandler`, which will print any `INFO` (or higher) message to `stderr`. This handler uses the `simple` output format.
  - `mail_admins`, an `AdminEmailHandler`, which will email any `ERROR` (or higher) message to the site admins. This handler uses the `special` filter.
- Configures three loggers:
  - `django`, which passes all messages to the `console` handler.
  - `django.request`, which passes all `ERROR` messages to the `mail_admins` handler. In addition, this logger is marked to *not* propagate messages. This means that log messages written to `django.request` will not be handled by the `django` logger.
  - `myproject.custom`, which passes all messages at `INFO` or higher that also pass the `special` filter to two handlers – the `console`, and `mail_admins`. This means that all `INFO` level messages (or higher) will be printed to the console; `ERROR` and `CRITICAL` messages will also be output via email.

## Custom logging configuration

If you don’t want to use Python’s dictConfig format to configure your logger, you can specify your own configuration scheme.

The `LOGGING_CONFIG` setting defines the callable that will be used to configure Django’s loggers. By default, it points at Python’s `logging.config.dictConfig()` function. However, if you want to use a different configuration process, you can use any other callable that takes a single argument. The contents of `LOGGING` will be provided as the value of that argument when logging is configured.

## Disabling logging configuration

If you don't want to configure logging at all (or you want to manually configure logging using your own approach), you can set `LOGGING_CONFIG` to `None`. This will disable the configuration process for *Django's default logging*. Here's an example that disables Django's logging configuration and then manually configures logging:

```
settings.py
LOGGING_CONFIG = None

import logging.config
logging.config.dictConfig(...)
```

Setting `LOGGING_CONFIG` to `None` only means that the automatic configuration process is disabled, not logging itself. If you disable the configuration process, Django will still make logging calls, falling back to whatever default logging behavior is defined.

### 3.16.4 Django's logging extensions

Django provides a number of utilities to handle the unique requirements of logging in Web server environment.

#### Loggers

Django provides several built-in loggers.

##### `django`

`django` is the catch-all logger. No messages are posted directly to this logger.

##### `django.request`

Log messages related to the handling of requests. 5XX responses are raised as `ERROR` messages; 4XX responses are raised as `WARNING` messages.

Messages to this logger have the following extra context:

- `status_code`: The HTTP response code associated with the request.
- `request`: The request object that generated the logging message.

##### `django.server`

Log messages related to the handling of requests received by the server invoked by the `runserver` command. HTTP 5XX responses are logged as `ERROR` messages, 4XX responses are logged as `WARNING` messages, and everything else is logged as `INFO`.

Messages to this logger have the following extra context:

- `status_code`: The HTTP response code associated with the request.
- `request`: The request object that generated the logging message.

### `django.template`

Log messages related to the rendering of templates.

- Missing context variables are logged as `DEBUG` messages.
- Uncaught exceptions raised during the rendering of an `{% include %}` are logged as `WARNING` messages when debug mode is off (helpful since `{% include %}` silences the exception and returns an empty string in that case).

### `django.db.backends`

Messages relating to the interaction of code with the database. For example, every application-level SQL statement executed by a request is logged at the `DEBUG` level to this logger.

Messages to this logger have the following extra context:

- `duration`: The time taken to execute the SQL statement.
- `sql`: The SQL statement that was executed.
- `params`: The parameters that were used in the SQL call.

For performance reasons, SQL logging is only enabled when `settings.DEBUG` is set to `True`, regardless of the logging level or handlers that are installed.

This logging does not include framework-level initialization (e.g. `SET TIMEZONE`) or transaction management queries (e.g. `BEGIN`, `COMMIT`, and `ROLLBACK`). Turn on query logging in your database if you wish to view all database queries.

### `django.security.*`

The security loggers will receive messages on any occurrence of `SuspiciousOperation`. There is a sub-logger for each sub-type of `SuspiciousOperation`. The level of the log event depends on where the exception is handled. Most occurrences are logged as a warning, while any `SuspiciousOperation` that reaches the WSGI handler will be logged as an error. For example, when an HTTP Host header is included in a request from a client that does not match `ALLOWED_HOSTS`, Django will return a 400 response, and an error message will be logged to the `django.security.DisallowedHost` logger.

These log events will reach the 'django' logger by default, which mails error events to admins when `DEBUG=False`. Requests resulting in a 400 response due to a `SuspiciousOperation` will not be logged to the `django.request` logger, but only to the `django.security` logger.

To silence a particular type of `SuspiciousOperation`, you can override that specific logger following this example:

```
'handlers': {
    'null': {
        'class': 'logging.NullHandler',
    },
},
'loggers': {
    'django.security.DisallowedHost': {
        'handlers': ['null'],
        'propagate': False,
    },
},
```

## `django.db.backends.schema`

Logs the SQL queries that are executed during schema changes to the database by the *migrations framework*. Note that it won't log the queries executed by *RunPython*. Messages to this logger have `params` and `sql` in their extra context (but unlike `django.db.backends`, not `duration`). The values have the same meaning as explained in *django.db.backends*.

The extra context was added.

## Handlers

Django provides one log handler in addition to those provided by the Python logging module.

**class `AdminEmailHandler`** (*include\_html=False, email\_backend=None*)

This handler sends an email to the site admins for each log message it receives.

If the log record contains a `request` attribute, the full details of the request will be included in the email. The email subject will include the phrase “internal IP” if the client’s IP address is in the `INTERNAL_IPS` setting; if not, it will include “EXTERNAL IP”.

If the log record contains stack trace information, that stack trace will be included in the email.

The `include_html` argument of `AdminEmailHandler` is used to control whether the traceback email includes an HTML attachment containing the full content of the debug Web page that would have been produced if `DEBUG` were `True`. To set this value in your configuration, include it in the handler definition for `django.utils.log.AdminEmailHandler`, like this:

```
'handlers': {
    'mail_admins': {
        'level': 'ERROR',
        'class': 'django.utils.log.AdminEmailHandler',
        'include_html': True,
    }
},
```

Note that this HTML version of the email contains a full traceback, with names and values of local variables at each level of the stack, plus the values of your Django settings. This information is potentially very sensitive, and you may not want to send it over email. Consider using something such as [Sentry](#) to get the best of both worlds – the rich information of full tracebacks plus the security of *not* sending the information over email. You may also explicitly designate certain sensitive information to be filtered out of error reports – learn more on [Filtering error reports](#).

By setting the `email_backend` argument of `AdminEmailHandler`, the *email backend* that is being used by the handler can be overridden, like this:

```
'handlers': {
    'mail_admins': {
        'level': 'ERROR',
        'class': 'django.utils.log.AdminEmailHandler',
        'email_backend': 'django.core.mail.backends.filebased.EmailBackend',
    }
},
```

By default, an instance of the email backend specified in `EMAIL_BACKEND` will be used.

**send\_mail** (*subject, message, \*args, \*\*kwargs*)

Sends emails to admin users. To customize this behavior, you can subclass the *AdminEmailHandler* class and override this method.

## Filters

Django provides two log filters in addition to those provided by the Python logging module.

### class `CallbackFilter` (*callback*)

This filter accepts a callback function (which should accept a single argument, the record to be logged), and calls it for each record that passes through the filter. Handling of that record will not proceed if the callback returns `False`.

For instance, to filter out `UnreadablePostError` (raised when a user cancels an upload) from the admin emails, you would create a filter function:

```
from django.http import UnreadablePostError

def skip_unreadable_post(record):
    if record.exc_info:
        exc_type, exc_value = record.exc_info[:2]
        if isinstance(exc_value, UnreadablePostError):
            return False
    return True
```

and then add it to your logging config:

```
'filters': {
    'skip_unreadable_posts': {
        '()': 'django.utils.log.CallbackFilter',
        'callback': skip_unreadable_post,
    }
},
'handlers': {
    'mail_admins': {
        'level': 'ERROR',
        'filters': ['skip_unreadable_posts'],
        'class': 'django.utils.log.AdminEmailHandler'
    }
},
```

### class `RequireDebugFalse`

This filter will only pass on records when settings.DEBUG is `False`.

This filter is used as follows in the default `LOGGING` configuration to ensure that the `AdminEmailHandler` only sends error emails to admins when `DEBUG` is `False`:

```
'filters': {
    'require_debug_false': {
        '()': 'django.utils.log.RequireDebugFalse',
    }
},
'handlers': {
    'mail_admins': {
        'level': 'ERROR',
        'filters': ['require_debug_false'],
        'class': 'django.utils.log.AdminEmailHandler'
    }
},
```

### class `RequireDebugTrue`

This filter is similar to `RequireDebugFalse`, except that records are passed only when `DEBUG` is `True`.

### 3.16.5 Django’s default logging configuration

By default, Django configures the following logging:

When `DEBUG` is `True`:

- The `django` catch-all logger sends all messages at the `INFO` level or higher to the console.

When `DEBUG` is `False`:

- The `django` logger send messages with `ERROR` or `CRITICAL` level to `AdminEmailHandler`.

Independent of the value of `DEBUG`:

- The `django.server` logger sends all messages at the `INFO` level or higher to the console.

Django’s default logging configuration changed. See [the release notes](#) for a description of the changes.

See also [Configuring logging](#) to learn how you can complement or replace this default logging configuration.

## 3.17 Pagination

Django provides a few classes that help you manage paginated data – that is, data that’s split across several pages, with “Previous/Next” links. These classes live in `django/core/paginator.py`.

### 3.17.1 Example

Give `Paginator` a list of objects, plus the number of items you’d like to have on each page, and it gives you methods for accessing the items for each page:

```
>>> from django.core.paginator import Paginator
>>> objects = ['john', 'paul', 'george', 'ringo']
>>> p = Paginator(objects, 2)

>>> p.count
4
>>> p.num_pages
2
>>> type(p.page_range) # `

```

```
>>> page2.next_page_number()
Traceback (most recent call last):
...
EmptyPage: That page contains no results
>>> page2.previous_page_number()
1
>>> page2.start_index() # The 1-based index of the first item on this page
3
>>> page2.end_index() # The 1-based index of the last item on this page
4

>>> p.page(0)
Traceback (most recent call last):
...
EmptyPage: That page number is less than 1
>>> p.page(3)
Traceback (most recent call last):
...
EmptyPage: That page contains no results
```

---

**Note:** Note that you can give `Paginator` a list/tuple, a Django `QuerySet`, or any other object with a `count()` or `__len__()` method. When determining the number of objects contained in the passed object, `Paginator` will first try calling `count()`, then fallback to using `len()` if the passed object has no `count()` method. This allows objects such as Django's `QuerySet` to use a more efficient `count()` method when available.

---

### 3.17.2 Using `Paginator` in a view

Here's a slightly more complex example using `Paginator` in a view to paginate a queryset. We give both the view and the accompanying template to show how you can display the results. This example assumes you have a `Contacts` model that has already been imported.

The view function looks like this:

```
from django.core.paginator import Paginator, EmptyPage, PageNotAnInteger
from django.shortcuts import render

def listing(request):
    contact_list = Contacts.objects.all()
    paginator = Paginator(contact_list, 25) # Show 25 contacts per page

    page = request.GET.get('page')
    try:
        contacts = paginator.page(page)
    except PageNotAnInteger:
        # If page is not an integer, deliver first page.
        contacts = paginator.page(1)
    except EmptyPage:
        # If page is out of range (e.g. 9999), deliver last page of results.
        contacts = paginator.page(paginator.num_pages)

    return render(request, 'list.html', {'contacts': contacts})
```

In the template `list.html`, you'll want to include navigation between pages along with any interesting information from the objects themselves:

```

{% for contact in contacts %}
    {# Each "contact" is a Contact model object. #}
    {{ contact.full_name|upper }}<br />
    ...
{% endfor %}

<div class="pagination">
    <span class="step-links">
        {% if contacts.has_previous %}
            <a href="?page={{ contacts.previous_page_number }}">previous</a>
        {% endif %}

        <span class="current">
            Page {{ contacts.number }} of {{ contacts.paginator.num_pages }}.
        </span>

        {% if contacts.has_next %}
            <a href="?page={{ contacts.next_page_number }}">next</a>
        {% endif %}
    </span>
</div>

```

### 3.17.3 Paginator objects

The *Paginator* class has this constructor:

```
class Paginator (object_list, per_page, orphans=0, allow_empty_first_page=True)
```

#### Required arguments

**object\_list** A list, tuple, QuerySet, or other sliceable object with a `count()` or `__len__()` method. For consistent pagination, QuerySets should be ordered, e.g. with an `order_by()` clause or with a default *ordering* on the model.

---

#### Performance issues paginating large QuerySets

If you're using a QuerySet with a very large number of items, requesting high page numbers might be slow on some databases, because the resulting LIMIT/OFFSET query needs to count the number of OFFSET records which takes longer as the page number gets higher.

---

**per\_page** The maximum number of items to include on a page, not including orphans (see the `orphans` optional argument below).

#### Optional arguments

**orphans** Use this when you don't want to have a last page with very few items. If the last page would normally have a number of items less than or equal to `orphans`, then those items will be added to the previous page (which becomes the last page) instead of leaving the items on a page by themselves. For example, with 23 items, `per_page=10`, and `orphans=3`, there will be two pages; the first page with 10 items and the second (and last) page with 13 items. `orphans` defaults to zero, which means pages are never combined and the last page may have one item.

**allow\_empty\_first\_page** Whether or not the first page is allowed to be empty. If `False` and `object_list` is empty, then an `EmptyPage` error will be raised.

## Methods

`Paginator.page(number)`

Returns a `Page` object with the given 1-based index. Raises `InvalidPage` if the given page number doesn't exist.

## Attributes

`Paginator.count`

The total number of objects, across all pages.

---

**Note:** When determining the number of objects contained in `object_list`, `Paginator` will first try calling `object_list.count()`. If `object_list` has no `count()` method, then `Paginator` will fallback to using `len(object_list)`. This allows objects, such as Django's `QuerySet`, to use a more efficient `count()` method when available.

---

`Paginator.num_pages`

The total number of pages.

`Paginator.page_range`

A 1-based range iterator of page numbers, e.g. yielding `[1, 2, 3, 4]`.

In older versions, `page_range` returned a list instead of an iterator.

## 3.17.4 InvalidPage exceptions

### exception `InvalidPage`

A base class for exceptions raised when a paginator is passed an invalid page number.

The `Paginator.page()` method raises an exception if the requested page is invalid (i.e., not an integer) or contains no objects. Generally, it's enough to catch the `InvalidPage` exception, but if you'd like more granularity, you can catch either of the following exceptions:

### exception `PageNotAnInteger`

Raised when `page()` is given a value that isn't an integer.

### exception `EmptyPage`

Raised when `page()` is given a valid value but no objects exist on that page.

Both of the exceptions are subclasses of `InvalidPage`, so you can handle them both with a simple `except InvalidPage`.

## 3.17.5 Page objects

You usually won't construct `Page` objects by hand – you'll get them using `Paginator.page()`.

**class `Page(object_list, number, paginator)`**

A page acts like a sequence of `Page.object_list` when using `len()` or iterating it directly.

## Methods

Page.**has\_next** ()

Returns True if there's a next page.

Page.**has\_previous** ()

Returns True if there's a previous page.

Page.**has\_other\_pages** ()

Returns True if there's a next *or* previous page.

Page.**next\_page\_number** ()

Returns the next page number. Raises *InvalidPage* if next page doesn't exist.

Page.**previous\_page\_number** ()

Returns the previous page number. Raises *InvalidPage* if previous page doesn't exist.

Page.**start\_index** ()

Returns the 1-based index of the first object on the page, relative to all of the objects in the paginator's list. For example, when paginating a list of 5 objects with 2 objects per page, the second page's *start\_index()* would return 3.

Page.**end\_index** ()

Returns the 1-based index of the last object on the page, relative to all of the objects in the paginator's list. For example, when paginating a list of 5 objects with 2 objects per page, the second page's *end\_index()* would return 4.

## Attributes

Page.**object\_list**

The list of objects on this page.

Page.**number**

The 1-based page number for this page.

Page.**paginator**

The associated *Paginator* object.

## 3.18 Porting to Python 3

Django 1.5 is the first version of Django to support Python 3. The same code runs both on Python 2 ( $\geq 2.6.5$ ) and Python 3 ( $\geq 3.2$ ), thanks to the *six* compatibility layer.

This document is primarily targeted at authors of pluggable applications who want to support both Python 2 and 3. It also describes guidelines that apply to Django's code.

### 3.18.1 Philosophy

This document assumes that you are familiar with the changes between Python 2 and Python 3. If you aren't, read [Python's official porting guide](#) first. Refreshing your knowledge of unicode handling on Python 2 and 3 will help; the [Pragmatic Unicode](#) presentation is a good resource.

Django uses the *Python 2/3 Compatible Source* strategy. Of course, you're free to choose another strategy for your own code, especially if you don't need to stay compatible with Python 2. But authors of pluggable applications are encouraged to use the same porting strategy as Django itself.

Writing compatible code is much easier if you target Python  $\geq 2.6$ . Django 1.5 introduces compatibility tools such as `django.utils.six`, which is a customized version of the `six` module. For convenience, forwards-compatible aliases were introduced in Django 1.4.2. If your application takes advantage of these tools, it will require Django  $\geq 1.4.2$ .

Obviously, writing compatible source code adds some overhead, and that can cause frustration. Django’s developers have found that attempting to write Python 3 code that’s compatible with Python 2 is much more rewarding than the opposite. Not only does that make your code more future-proof, but Python 3’s advantages (like the saner string handling) start shining quickly. Dealing with Python 2 becomes a backwards compatibility requirement, and we as developers are used to dealing with such constraints.

Porting tools provided by Django are inspired by this philosophy, and it’s reflected throughout this guide.

## 3.18.2 Porting tips

### Unicode literals

This step consists in:

- Adding `from __future__ import unicode_literals` at the top of your Python modules – it’s best to put it in each and every module, otherwise you’ll keep checking the top of your files to see which mode is in effect;
- Removing the `u` prefix before unicode strings;
- Adding a `b` prefix before bytestrings.

Performing these changes systematically guarantees backwards compatibility.

However, Django applications generally don’t need bytestrings, since Django only exposes unicode interfaces to the programmer. Python 3 discourages using bytestrings, except for binary data or byte-oriented interfaces. Python 2 makes bytestrings and unicode strings effectively interchangeable, as long as they only contain ASCII data. Take advantage of this to use unicode strings wherever possible and avoid the `b` prefixes.

---

**Note:** Python 2’s `u` prefix is a syntax error in Python 3.2 but it will be allowed again in Python 3.3 thanks to [PEP 414](#). Thus, this transformation is optional if you target Python  $\geq 3.3$ . It’s still recommended, per the “write Python 3 code” philosophy.

---

### String handling

Python 2’s `unicode` type was renamed `str` in Python 3, `str()` was renamed `bytes`, and `basestring` disappeared. `six` provides `tools` to deal with these changes.

Django also contains several string related classes and functions in the `django.utils.encoding` and `django.utils.safestring` modules. Their names used the words `str`, which doesn’t mean the same thing in Python 2 and Python 3, and `unicode`, which doesn’t exist in Python 3. In order to avoid ambiguity and confusion these concepts were renamed `bytes` and `text`.

Here are the name changes in `django.utils.encoding`:

Old name	New name
<code>smart_str</code>	<code>smart_bytes</code>
<code>smart_unicode</code>	<code>smart_text</code>
<code>force_unicode</code>	<code>force_text</code>

For backwards compatibility, the old names still work on Python 2. Under Python 3, `smart_str` is an alias for `smart_text`.

For forwards compatibility, the new names work as of Django 1.4.2.

---

**Note:** `django.utils.encoding` was deeply refactored in Django 1.5 to provide a more consistent API. Check its documentation for more information.

---

`django.utils.safestring` is mostly used via the `mark_safe()` and `mark_for_escaping()` functions, which didn't change. In case you're using the internals, here are the name changes:

Old name	New name
<code>EscapeString</code>	<code>EscapeBytes</code>
<code>EscapeUnicode</code>	<code>EscapeText</code>
<code>SafeString</code>	<code>SafeBytes</code>
<code>SafeUnicode</code>	<code>SafeText</code>

For backwards compatibility, the old names still work on Python 2. Under Python 3, `EscapeString` and `SafeString` are aliases for `EscapeText` and `SafeText` respectively.

For forwards compatibility, the new names work as of Django 1.4.2.

### `__str__()` and `__unicode__()` methods

In Python 2, the object model specifies `__str__()` and `__unicode__()` methods. If these methods exist, they must return `str` (bytes) and `unicode` (text) respectively.

The `print` statement and the `str` built-in call `__str__()` to determine the human-readable representation of an object. The `unicode` built-in calls `__unicode__()` if it exists, and otherwise falls back to `__str__()` and decodes the result with the system encoding. Conversely, the `Model` base class automatically derives `__str__()` from `__unicode__()` by encoding to UTF-8.

In Python 3, there's simply `__str__()`, which must return `str` (text).

(It is also possible to define `__bytes__()`, but Django applications have little use for that method, because they hardly ever deal with `bytes`.)

Django provides a simple way to define `__str__()` and `__unicode__()` methods that work on Python 2 and 3: you must define a `__str__()` method returning text and to apply the `python_2_unicode_compatible()` decorator.

On Python 3, the decorator is a no-op. On Python 2, it defines appropriate `__unicode__()` and `__str__()` methods (replacing the original `__str__()` method in the process). Here's an example:

```
from __future__ import unicode_literals
from django.utils.encoding import python_2_unicode_compatible

@python_2_unicode_compatible
class MyClass(object):
    def __str__(self):
        return "Instance of my class"
```

This technique is the best match for Django's porting philosophy.

For forwards compatibility, this decorator is available as of Django 1.4.2.

Finally, note that `__repr__()` must return a `str` on all versions of Python.

## dict and dict-like classes

`dict.keys()`, `dict.items()` and `dict.values()` return lists in Python 2 and iterators in Python 3. `QueryDict` and the dict-like classes defined in `django.utils.datastructures` behave likewise in Python 3.

`six` provides compatibility functions to work around this change: `iterkeys()`, `iteritems()`, and `itervalues()`. It also contains an undocumented `iterlists` function that works well for `django.utils.datastructures.MultiValueDict` and its subclasses.

## HttpRequest and HttpResponse objects

According to [PEP 3333](#):

- headers are always `str` objects,
- input and output streams are always `bytes` objects.

Specifically, `HttpResponse.content` contains `bytes`, which may become an issue if you compare it with a `str` in your tests. The preferred solution is to rely on `assertContains()` and `assertNotContains()`. These methods accept a response and a unicode string as arguments.

### 3.18.3 Coding guidelines

The following guidelines are enforced in Django's source code. They're also recommended for third-party applications that follow the same porting strategy.

#### Syntax requirements

##### Unicode

In Python 3, all strings are considered Unicode by default. The `unicode` type from Python 2 is called `str` in Python 3, and `str` becomes `bytes`.

You mustn't use the `u` prefix before a unicode string literal because it's a syntax error in Python 3.2. You must prefix byte strings with `b`.

In order to enable the same behavior in Python 2, every module must import `unicode_literals` from `__future__`:

```
from __future__ import unicode_literals

my_string = "This is an unicode literal"
my_bytestring = b"This is a bytestring"
```

If you need a byte string literal under Python 2 and a unicode string literal under Python 3, use the `str` builtin:

```
str('my string')
```

In Python 3, there aren't any automatic conversions between `str` and `bytes`, and the `codecs` module became more strict. `str.encode()` always returns `bytes`, and `bytes.decode` always returns `str`. As a consequence, the following pattern is sometimes necessary:

```
value = value.encode('ascii', 'ignore').decode('ascii')
```

Be cautious if you have to index `bytestrings`.

## Exceptions

When you capture exceptions, use the `as` keyword:

```
try:
    ...
except MyException as exc:
    ...
```

This older syntax was removed in Python 3:

```
try:
    ...
except MyException, exc:    # Don't do that!
    ...
```

The syntax to reraise an exception with a different traceback also changed. Use `six.reraise()`.

## Magic methods

Use the patterns below to handle magic methods renamed in Python 3.

### Iterators

```
class MyIterator(six.Iterator):
    def __iter__(self):
        return self          # implement some logic here

    def __next__(self):
        raise StopIteration  # implement some logic here
```

### Boolean evaluation

```
class MyBoolean(object):

    def __bool__(self):
        return True          # implement some logic here

    def __nonzero__(self):   # Python 2 compatibility
        return type(self).__bool__(self)
```

### Division

```
class MyDivisible(object):

    def __truediv__(self, other):
        return self / other  # implement some logic here

    def __div__(self, other): # Python 2 compatibility
        return type(self).__truediv__(self, other)
```

```
def __itruediv__(self, other):
    return self // other    # implement some logic here

def __idiv__(self, other): # Python 2 compatibility
    return type(self).__itruediv__(self, other)
```

Special methods are looked up on the class and not on the instance to reflect the behavior of the Python interpreter.

## Writing compatible code with six

`six` is the canonical compatibility library for supporting Python 2 and 3 in a single codebase. Read its documentation!

A *customized version of six* is bundled with Django as of version 1.4.2. You can import it as `django.utils.six`.

Here are the most common changes required to write compatible code.

## String handling

The `basestring` and `unicode` types were removed in Python 3, and the meaning of `str` changed. To test these types, use the following idioms:

```
isinstance(myvalue, six.string_types)    # replacement for basestring
isinstance(myvalue, six.text_type)       # replacement for unicode
isinstance(myvalue, bytes)               # replacement for str
```

Python  $\geq$  2.6 provides `bytes` as an alias for `str`, so you don't need `six.binary_type`.

## long

The `long` type no longer exists in Python 3. `1L` is a syntax error. Use `six.integer_types` check if a value is an integer or a long:

```
isinstance(myvalue, six.integer_types)    # replacement for (int, long)
```

## xrange

If you use `xrange` on Python 2, import `six.moves.range` and use that instead. You can also import `six.moves.xrange` (it's equivalent to `six.moves.range`) but the first technique allows you to simply drop the import when dropping support for Python 2.

## Moved modules

Some modules were renamed in Python 3. The `django.utils.six.moves` module (based on the `six.moves` module) provides a compatible location to import them.

## PY2

If you need different code in Python 2 and Python 3, check `six.PY2`:

```
if six.PY2:
    # compatibility code for Python 2
```

This is a last resort solution when `six` doesn't provide an appropriate function.

## Django customized version of `six`

The version of `six` bundled with Django (`django.utils.six`) includes a few customizations for internal use only.

## 3.19 Security in Django

This document is an overview of Django's security features. It includes advice on securing a Django-powered site.

### 3.19.1 Cross site scripting (XSS) protection

XSS attacks allow a user to inject client side scripts into the browsers of other users. This is usually achieved by storing the malicious scripts in the database where it will be retrieved and displayed to other users, or by getting users to click a link which will cause the attacker's JavaScript to be executed by the user's browser. However, XSS attacks can originate from any untrusted source of data, such as cookies or Web services, whenever the data is not sufficiently sanitized before including in a page.

Using Django templates protects you against the majority of XSS attacks. However, it is important to understand what protections it provides and its limitations.

Django templates *escape specific characters* which are particularly dangerous to HTML. While this protects users from most malicious input, it is not entirely foolproof. For example, it will not protect the following:

```
<style class={{ var }}>...</style>
```

If `var` is set to `'class1 onmouseover=javascript:func()'`, this can result in unauthorized JavaScript execution, depending on how the browser renders imperfect HTML. (Quoting the attribute value would fix this case.)

It is also important to be particularly careful when using `is_safe` with custom template tags, the `safe` template tag, `mark_safe`, and when `autoescape` is turned off.

In addition, if you are using the template system to output something other than HTML, there may be entirely separate characters and words which require escaping.

You should also be very careful when storing HTML in the database, especially when that HTML is retrieved and displayed.

### 3.19.2 Cross site request forgery (CSRF) protection

CSRF attacks allow a malicious user to execute actions using the credentials of another user without that user's knowledge or consent.

Django has built-in protection against most types of CSRF attacks, providing you have *enabled and used it* where appropriate. However, as with any mitigation technique, there are limitations. For example, it is possible to disable

the CSRF module globally or for particular views. You should only do this if you know what you are doing. There are other *limitations* if your site has subdomains that are outside of your control.

*CSRF protection works* by checking for a secret in each POST request. This ensures that a malicious user cannot simply “replay” a form POST to your website and have another logged in user unwittingly submit that form. The malicious user would have to know the secret, which is user specific (using a cookie).

When deployed with *HTTPS*, `CsrfViewMiddleware` will check that the HTTP referer header is set to a URL on the same origin (including subdomain and port). Because HTTPS provides additional security, it is imperative to ensure connections use HTTPS where it is available by forwarding insecure connection requests and using HSTS for supported browsers.

Be very careful with marking views with the `csrf_exempt` decorator unless it is absolutely necessary.

### 3.19.3 SQL injection protection

SQL injection is a type of attack where a malicious user is able to execute arbitrary SQL code on a database. This can result in records being deleted or data leakage.

By using Django’s queriesets, the resulting SQL will be properly escaped by the underlying database driver. However, Django also gives developers power to write *raw queries* or execute *custom sql*. These capabilities should be used sparingly and you should always be careful to properly escape any parameters that the user can control. In addition, you should exercise caution when using `extra()` and `RawSQL`.

### 3.19.4 Clickjacking protection

Clickjacking is a type of attack where a malicious site wraps another site in a frame. This attack can result in an unsuspecting user being tricked into performing unintended actions on the target site.

Django contains *clickjacking protection* in the form of the `X-Frame-Options` *middleware* which in a supporting browser can prevent a site from being rendered inside a frame. It is possible to disable the protection on a per view basis or to configure the exact header value sent.

The middleware is strongly recommended for any site that does not need to have its pages wrapped in a frame by third party sites, or only needs to allow that for a small section of the site.

### 3.19.5 SSL/HTTPS

It is always better for security to deploy your site behind HTTPS. Without this, it is possible for malicious network users to sniff authentication credentials or any other information transferred between client and server, and in some cases – **active** network attackers – to alter data that is sent in either direction.

If you want the protection that HTTPS provides, and have enabled it on your server, there are some additional steps you may need:

- If necessary, set `SECURE_PROXY_SSL_HEADER`, ensuring that you have understood the warnings there thoroughly. Failure to do this can result in CSRF vulnerabilities, and failure to do it correctly can also be dangerous!
- Set `SECURE_SSL_REDIRECT` to `True`, so that requests over HTTP are redirected to HTTPS.

Please note the caveats under `SECURE_PROXY_SSL_HEADER`. For the case of a reverse proxy, it may be easier or more secure to configure the main Web server to do the redirect to HTTPS.

- Use ‘secure’ cookies.

If a browser connects initially via HTTP, which is the default for most browsers, it is possible for existing cookies to be leaked. For this reason, you should set your `SESSION_COOKIE_SECURE` and

`CSRF_COOKIE_SECURE` settings to `True`. This instructs the browser to only send these cookies over HTTPS connections. Note that this will mean that sessions will not work over HTTP, and the CSRF protection will prevent any POST data being accepted over HTTP (which will be fine if you are redirecting all HTTP traffic to HTTPS).

- Use *HTTP Strict Transport Security* (HSTS)

HSTS is an HTTP header that informs a browser that all future connections to a particular site should always use HTTPS. Combined with redirecting requests over HTTP to HTTPS, this will ensure that connections always enjoy the added security of SSL provided one successful connection has occurred. HSTS may either be configured with `SECURE_HSTS_SECONDS` and `SECURE_HSTS_INCLUDE_SUBDOMAINS` or on the Web server.

### 3.19.6 Host header validation

Django uses the `Host` header provided by the client to construct URLs in certain cases. While these values are sanitized to prevent Cross Site Scripting attacks, a fake `Host` value can be used for Cross-Site Request Forgery, cache poisoning attacks, and poisoning links in emails.

Because even seemingly-secure web server configurations are susceptible to fake `Host` headers, Django validates `Host` headers against the `ALLOWED_HOSTS` setting in the `django.http.HttpRequest.get_host()` method.

This validation only applies via `get_host()`; if your code accesses the `Host` header directly from `request.META` you are bypassing this security protection.

For more details see the full `ALLOWED_HOSTS` documentation.

**Warning:** Previous versions of this document recommended configuring your web server to ensure it validates incoming HTTP `Host` headers. While this is still recommended, in many common web servers a configuration that seems to validate the `Host` header may not in fact do so. For instance, even if Apache is configured such that your Django site is served from a non-default virtual host with the `ServerName` set, it is still possible for an HTTP request to match this virtual host and supply a fake `Host` header. Thus, Django now requires that you set `ALLOWED_HOSTS` explicitly rather than relying on web server configuration.

Additionally, Django requires you to explicitly enable support for the `X-Forwarded-Host` header (via the `USE_X_FORWARDED_HOST` setting) if your configuration requires it.

### 3.19.7 Session security

Similar to the *CSRF limitations* requiring a site to be deployed such that untrusted users don't have access to any subdomains, `django.contrib.sessions` also has limitations. See *the session topic guide section on security* for details.

### 3.19.8 User-uploaded content

---

**Note:** Consider *servicing static files from a cloud service or CDN* to avoid some of these issues.

---

- If your site accepts file uploads, it is strongly advised that you limit these uploads in your Web server configuration to a reasonable size in order to prevent denial of service (DOS) attacks. In Apache, this can be easily set using the `LimitRequestBody` directive.

- If you are serving your own static files, be sure that handlers like Apache's `mod_php`, which would execute static files as code, are disabled. You don't want users to be able to execute arbitrary code by uploading and requesting a specially crafted file.
- Django's media upload handling poses some vulnerabilities when that media is served in ways that do not follow security best practices. Specifically, an HTML file can be uploaded as an image if that file contains a valid PNG header followed by malicious HTML. This file will pass verification of the library that Django uses for `ImageField` image processing (Pillow). When this file is subsequently displayed to a user, it may be displayed as HTML depending on the type and configuration of your web server.

No bulletproof technical solution exists at the framework level to safely validate all user uploaded file content, however, there are some other steps you can take to mitigate these attacks:

1. One class of attacks can be prevented by always serving user uploaded content from a distinct top-level or second-level domain. This prevents any exploit blocked by [same-origin policy](#) protections such as cross site scripting. For example, if your site runs on `example.com`, you would want to serve uploaded content (the `MEDIA_URL` setting) from something like `usercontent-example.com`. It's *not* sufficient to serve content from a subdomain like `usercontent.example.com`.
2. Beyond this, applications may choose to define a whitelist of allowable file extensions for user uploaded files and configure the web server to only serve such files.

### 3.19.9 Additional security topics

While Django provides good security protection out of the box, it is still important to properly deploy your application and take advantage of the security protection of the Web server, operating system and other components.

- Make sure that your Python code is outside of the Web server's root. This will ensure that your Python code is not accidentally served as plain text (or accidentally executed).
- Take care with any *user uploaded files*.
- Django does not throttle requests to authenticate users. To protect against brute-force attacks against the authentication system, you may consider deploying a Django plugin or Web server module to throttle these requests.
- Keep your `SECRET_KEY` a secret.
- It is a good idea to limit the accessibility of your caching system and database using a firewall.
- Take a look at the Open Web Application Security Project (OWASP) [Top 10 list](#) which identifies some common vulnerabilities in web applications. While Django has tools to address some of the issues, other issues must be accounted for in the design of your project.

## 3.20 Performance and optimization

This document provides an overview of techniques and tools that can help get your Django code running more efficiently - faster, and using fewer system resources.

### 3.20.1 Introduction

Generally one's first concern is to write code that *works*, whose logic functions as required to produce the expected output. Sometimes, however, this will not be enough to make the code work as *efficiently* as one would like.

In this case, what's needed is something - and in practice, often a collection of things - to improve the code's performance without, or only minimally, affecting its behavior.

## 3.20.2 General approaches

### What are you optimizing *for*?

It's important to have a clear idea what you mean by 'performance'. There is not just one metric of it.

Improved speed might be the most obvious aim for a program, but sometimes other performance improvements might be sought, such as lower memory consumption or fewer demands on the database or network.

Improvements in one area will often bring about improved performance in another, but not always; sometimes one can even be at the expense of another. For example, an improvement in a program's speed might cause it to use more memory. Even worse, it can be self-defeating - if the speed improvement is so memory-hungry that the system starts to run out of memory, you'll have done more harm than good.

There are other trade-offs to bear in mind. Your own time is a valuable resource, more precious than CPU time. Some improvements might be too difficult to be worth implementing, or might affect the portability or maintainability of the code. Not all performance improvements are worth the effort.

So, you need to know what performance improvements you are aiming for, and you also need to know that you have a good reason for aiming in that direction - and for that you need:

### Performance benchmarking

It's no good just guessing or assuming where the inefficiencies lie in your code.

### Django tools

`django-debug-toolbar` is a very handy tool that provides insights into what your code is doing and how much time it spends doing it. In particular it can show you all the SQL queries your page is generating, and how long each one has taken.

Third-party panels are also available for the toolbar, that can (for example) report on cache performance and template rendering times.

### Third-party services

There are a number of free services that will analyze and report on the performance of your site's pages from the perspective of a remote HTTP client, in effect simulating the experience of an actual user.

These can't report on the internals of your code, but can provide a useful insight into your site's overall performance, including aspects that can't be adequately measured from within Django environment. Examples include:

- [Yahoo's Yslow](#)
- [Google PageSpeed](#)

There are also several paid-for services that perform a similar analysis, including some that are Django-aware and can integrate with your codebase to profile its performance far more comprehensively.

### Get things right from the start

Some work in optimization involves tackling performance shortcomings, but some of the work can simply be built in to what you'd do anyway, as part of the good practices you should adopt even before you start thinking about improving performance.

In this respect Python is an excellent language to work with, because solutions that look elegant and feel right usually are the best performing ones. As with most skills, learning what “looks right” takes practice, but one of the most useful guidelines is:

### Work at the appropriate level

Django offers many different ways of approaching things, but just because it’s possible to do something in a certain way doesn’t mean that it’s the most appropriate way to do it. For example, you might find that you could calculate the same thing - the number of items in a collection, perhaps - in a `QuerySet`, in Python, or in a template.

However, it will almost always be faster to do this work at lower rather than higher levels. At higher levels the system has to deal with objects through multiple levels of abstraction and layers of machinery.

That is, the database can typically do things faster than Python can, which can do them faster than the template language can:

```
# QuerySet operation on the database
# fast, because that's what databases are good at
my_bicycles.count()

# counting Python objects
# slower, because it requires a database query anyway, and processing
# of the Python objects
len(my_bicycles)

# Django template filter
# slower still, because it will have to count them in Python anyway,
# and because of template language overheads
{{ my_bicycles|length }}
```

Generally speaking, the most appropriate level for the job is the lowest-level one that it is comfortable to code for.

---

**Note:** The example above is merely illustrative.

Firstly, in a real-life case you need to consider what is happening before and after your count to work out what’s an optimal way of doing it *in that particular context*. The database optimization documents describes *a case where counting in the template would be better*.

Secondly, there are other options to consider: in a real-life case, `{{ my_bicycles.count }}`, which invokes the `QuerySet count()` method directly from the template, might be the most appropriate choice.

---

## 3.20.3 Caching

Often it is expensive (that is, resource-hungry and slow) to compute a value, so there can be huge benefit in saving the value to a quickly accessible cache, ready for the next time it’s required.

It’s a sufficiently significant and powerful technique that Django includes a comprehensive caching framework, as well as other smaller pieces of caching functionality.

### The caching framework

Django’s *caching framework* offers very significant opportunities for performance gains, by saving dynamic content so that it doesn’t need to be calculated for each request.

For convenience, Django offers different levels of cache granularity: you can cache the output of specific views, or only the pieces that are difficult to produce, or even an entire site.

Implementing caching should not be regarded as an alternative to improving code that's performing poorly because it has been written badly. It's one of the final steps towards producing well-performing code, not a shortcut.

### `cached_property`

It's common to have to call a class instance's method more than once. If that function is expensive, then doing so can be wasteful.

Using the `cached_property` decorator saves the value returned by a property; the next time the function is called on that instance, it will return the saved value rather than re-computing it. Note that this only works on methods that take `self` as their only argument and that it changes the method to a property.

Certain Django components also have their own caching functionality; these are discussed below in the sections related to those components.

## 3.20.4 Understanding laziness

*Laziness* is a strategy complementary to caching. Caching avoids recomputation by saving results; laziness delays computation until it's actually required.

Laziness allows us to refer to things before they are instantiated, or even before it's possible to instantiate them. This has numerous uses.

For example, *lazy translation* can be used before the target language is even known, because it doesn't take place until the translated string is actually required, such as in a rendered template.

Laziness is also a way to save effort by trying to avoid work in the first place. That is, one aspect of laziness is not doing anything until it has to be done, because it may not turn out to be necessary after all. Laziness can therefore have performance implications, and the more expensive the work concerned, the more there is to gain through laziness.

Python provides a number of tools for lazy evaluation, particularly through the `generator` and `generator expression` constructs. It's worth reading up on laziness in Python to discover opportunities for making use of lazy patterns in your code.

### Laziness in Django

Django is itself quite lazy. A good example of this can be found in the evaluation of `QuerySets`. *QuerySets are lazy*. Thus a `QuerySet` can be created, passed around and combined with other `QuerySets`, without actually incurring any trips to the database to fetch the items it describes. What gets passed around is the `QuerySet` object, not the collection of items that - eventually - will be required from the database.

On the other hand, *certain operations will force the evaluation of a QuerySet*. Avoiding the premature evaluation of a `QuerySet` can save making an expensive and unnecessary trip to the database.

Django also offers a `keep_lazy()` decorator. This allows a function that has been called with a lazy argument to behave lazily itself, only being evaluated when it needs to be. Thus the lazy argument - which could be an expensive one - will not be called upon for evaluation until it's strictly required.

## 3.20.5 Databases

### Database optimization

Django’s database layer provides various ways to help developers get the best performance from their databases. The *database optimization documentation* gathers together links to the relevant documentation and adds various tips that outline the steps to take when attempting to optimize your database usage.

### Other database-related tips

Enabling *Persistent connections* can speed up connections to the database accounts for a significant part of the request processing time.

This helps a lot on virtualized hosts with limited network performance, for example.

## 3.20.6 HTTP performance

### Middleware

Django comes with a few helpful pieces of *middleware* that can help optimize your site’s performance. They include:

#### `ConditionalGetMiddleware`

Adds support for modern browsers to conditionally GET responses based on the ETag and Last-Modified headers.

#### `GZipMiddleware`

Compresses responses for all modern browsers, saving bandwidth and transfer time. Note that `GZipMiddleware` is currently considered a security risk, and is vulnerable to attacks that nullify the protection provided by TLS/SSL. See the warning in *GZipMiddleware* for more information.

### Sessions

#### Using cached sessions

*Using cached sessions* may be a way to increase performance by eliminating the need to load session data from a slower storage source like the database and instead storing frequently used session data in memory.

### Static files

Static files, which by definition are not dynamic, make an excellent target for optimization gains.

## CachedStaticFilesStorage

By taking advantage of web browsers' caching abilities, you can eliminate network hits entirely for a given file after the initial download.

*CachedStaticFilesStorage* appends a content-dependent tag to the filenames of *static files* to make it safe for browsers to cache them long-term without missing future changes - when a file changes, so will the tag, so browsers will reload the asset automatically.

### “Minification”

Several third-party Django tools and packages provide the ability to “minify” HTML, CSS, and JavaScript. They remove unnecessary whitespace, newlines, and comments, and shorten variable names, and thus reduce the size of the documents that your site publishes.

## 3.20.7 Template performance

Note that:

- using `{% block %}` is faster than using `{% include %}`
- heavily-fragmented templates, assembled from many small pieces, can affect performance

### The cached template loader

Enabling the *cached template loader* often improves performance drastically, as it avoids compiling each template every time it needs to be rendered.

## 3.20.8 Using different versions of available software

It can sometimes be worth checking whether different and better-performing versions of the software that you're using are available.

These techniques are targeted at more advanced users who want to push the boundaries of performance of an already well-optimized Django site.

However, they are not magic solutions to performance problems, and they're unlikely to bring better than marginal gains to sites that don't already do the more basic things the right way.

---

**Note:** It's worth repeating: **reaching for alternatives to software you're already using is never the first answer to performance problems.** When you reach this level of optimization, you need a formal benchmarking solution.

---

### Newer is often - but not always - better

It's fairly rare for a new release of well-maintained software to be less efficient, but the maintainers can't anticipate every possible use-case - so while being aware that newer versions are likely to perform better, don't simply assume that they always will.

This is true of Django itself. Successive releases have offered a number of improvements across the system, but you should still check the real-world performance of your application, because in some cases you may find that changes mean it performs worse rather than better.

Newer versions of Python, and also of Python packages, will often perform better too - but measure, rather than assume.

---

**Note:** Unless you've encountered an unusual performance problem in a particular version, you'll generally find better features, reliability, and security in a new release and that these benefits are far more significant than any performance you might win or lose.

---

## Alternatives to Django's template language

For nearly all cases, Django's built-in template language is perfectly adequate. However, if the bottlenecks in your Django project seem to lie in the template system and you have exhausted other opportunities to remedy this, a third-party alternative may be the answer.

Jinja2 can offer performance improvements, particularly when it comes to speed.

Alternative template systems vary in the extent to which they share Django's templating language.

---

**Note:** *If* you experience performance issues in templates, the first thing to do is to understand exactly why. Using an alternative template system may prove faster, but the same gains may also be available without going to that trouble - for example, expensive processing and logic in your templates could be done more efficiently in your views.

---

## Alternative software implementations

It may be worth checking whether Python software you're using has been provided in a different implementation that can execute the same code faster.

However: most performance problems in well-written Django sites aren't at the Python execution level, but rather in inefficient database querying, caching, and templates. If you're relying on poorly-written Python code, your performance problems are unlikely to be solved by having it execute faster.

Using an alternative implementation may introduce compatibility, deployment, portability, or maintenance issues. It goes without saying that before adopting a non-standard implementation you should ensure it provides sufficient performance gains for your application to outweigh the potential risks.

With these caveats in mind, you should be aware of:

### PyPy

PyPy is an implementation of Python in Python itself (the 'standard' Python implementation is in C). PyPy can offer substantial performance gains, typically for heavyweight applications.

A key aim of the PyPy project is [compatibility](#) with existing Python APIs and libraries. Django is compatible, but you will need to check the compatibility of other libraries you rely on.

### C implementations of Python libraries

Some Python libraries are also implemented in C, and can be much faster. They aim to offer the same APIs. Note that compatibility issues and behavior differences are not unknown (and not always immediately evident).

## 3.21 Serializing Django objects

Django’s serialization framework provides a mechanism for “translating” Django models into other formats. Usually these other formats will be text-based and used for sending Django data over a wire, but it’s possible for a serializer to handle any format (text-based or not).

### See also:

If you just want to get some data from your tables into a serialized form, you could use the `dumpdata` management command.

### 3.21.1 Serializing data

At the highest level, serializing data is a very simple operation:

```
from django.core import serializers
data = serializers.serialize("xml", SomeModel.objects.all())
```

The arguments to the `serialize` function are the format to serialize the data to (see *Serialization formats*) and a *QuerySet* to serialize. (Actually, the second argument can be any iterator that yields Django model instances, but it’ll almost always be a *QuerySet*).

```
django.core.serializers.get_serializer(format)
```

You can also use a serializer object directly:

```
XMLSerializer = serializers.get_serializer("xml")
xml_serializer = XMLSerializer()
xml_serializer.serialize(queryset)
data = xml_serializer.getvalue()
```

This is useful if you want to serialize data directly to a file-like object (which includes an *HttpResponse*):

```
with open("file.xml", "w") as out:
    xml_serializer.serialize(SomeModel.objects.all(), stream=out)
```

---

**Note:** Calling `get_serializer()` with an unknown *format* will raise a `django.core.serializers.SerializerDoesNotExist` exception.

---

### Subset of fields

If you only want a subset of fields to be serialized, you can specify a `fields` argument to the serializer:

```
from django.core import serializers
data = serializers.serialize('xml', SomeModel.objects.all(), fields=('name', 'size'))
```

In this example, only the `name` and `size` attributes of each model will be serialized. The primary key is always serialized as the `pk` element in the resulting output; it never appears in the `fields` part.

---

**Note:** Depending on your model, you may find that it is not possible to deserialize a model that only serializes a subset of its fields. If a serialized object doesn’t specify all the fields that are required by a model, the deserializer will not be able to save deserialized instances.

---

## Inherited models

If you have a model that is defined using an *abstract base class*, you don't have to do anything special to serialize that model. Just call the serializer on the object (or objects) that you want to serialize, and the output will be a complete representation of the serialized object.

However, if you have a model that uses *multi-table inheritance*, you also need to serialize all of the base classes for the model. This is because only the fields that are locally defined on the model will be serialized. For example, consider the following models:

```
class Place(models.Model):
    name = models.CharField(max_length=50)

class Restaurant(Place):
    serves_hot_dogs = models.BooleanField(default=False)
```

If you only serialize the Restaurant model:

```
data = serializers.serialize('xml', Restaurant.objects.all())
```

the fields on the serialized output will only contain the `serves_hot_dogs` attribute. The `name` attribute of the base class will be ignored.

In order to fully serialize your Restaurant instances, you will need to serialize the Place models as well:

```
all_objects = list(Restaurant.objects.all()) + list(Place.objects.all())
data = serializers.serialize('xml', all_objects)
```

### 3.21.2 Deserializing data

Deserializing data is also a fairly simple operation:

```
for obj in serializers.deserialize("xml", data):
    do_something_with(obj)
```

As you can see, the `deserialize` function takes the same format argument as `serialize`, a string or stream of data, and returns an iterator.

However, here it gets slightly complicated. The objects returned by the `deserialize` iterator *aren't* simple Django objects. Instead, they are special `DeserializedObject` instances that wrap a created – but unsaved – object and any associated relationship data.

Calling `DeserializedObject.save()` saves the object to the database.

---

**Note:** If the `pk` attribute in the serialized data doesn't exist or is null, a new instance will be saved to the database.

---

This ensures that deserializing is a non-destructive operation even if the data in your serialized representation doesn't match what's currently in the database. Usually, working with these `DeserializedObject` instances looks something like:

```
for deserialized_object in serializers.deserialize("xml", data):
    if object_should_be_saved(deserialized_object):
        deserialized_object.save()
```

In other words, the usual use is to examine the deserialized objects to make sure that they are “appropriate” for saving before doing so. Of course, if you trust your data source you could just save the object and move on.

The Django object itself can be inspected as `deserialized_object.object`. If fields in the serialized data do not exist on a model, a `DeserializationError` will be raised unless the `ignorenonexistent` argument is passed in as `True`:

```
serializers.deserialize("xml", data, ignorenonexistent=True)
```

### 3.21.3 Serialization formats

Django supports a number of serialization formats, some of which require you to install third-party Python modules:

Identifier	Information
xml	Serializes to and from a simple XML dialect.
json	Serializes to and from JSON.
yaml	Serializes to YAML (YAML Ain't a Markup Language). This serializer is only available if PyYAML is installed.

#### XML

The basic XML serialization format is quite simple:

```
<?xml version="1.0" encoding="utf-8"?>
<django-objects version="1.0">
  <object pk="123" model="sessions.session">
    <field type="DateTimeField" name="expire_date">2013-01-16T08:16:59.
    ↪844560+00:00</field>
    <!-- ... -->
  </object>
</django-objects>
```

The whole collection of objects that is either serialized or de-serialized is represented by a `<django-objects>`-tag which contains multiple `<object>`-elements. Each such object has two attributes: “pk” and “model”, the latter being represented by the name of the app (“sessions”) and the lowercase name of the model (“session”) separated by a dot.

Each field of the object is serialized as a `<field>`-element sporting the fields “type” and “name”. The text content of the element represents the value that should be stored.

Foreign keys and other relational fields are treated a little bit differently:

```
<object pk="27" model="auth.permission">
  <!-- ... -->
  <field to="contenttypes.contenttype" name="content_type" rel="ManyToOneRel">9</
  ↪field>
  <!-- ... -->
</object>
```

In this example we specify that the `auth.Permission` object with the PK 27 has a foreign key to the `contenttypes.ContentType` instance with the PK 9.

ManyToMany-relations are exported for the model that binds them. For instance, the `auth.User` model has such a relation to the `auth.Permission` model:

```
<object pk="1" model="auth.user">
  <!-- ... -->
  <field to="auth.permission" name="user_permissions" rel="ManyToManyRel">
    <object pk="46"></object>
```

```
<object pk="47"></object>
</field>
</object>
```

This example links the given user with the permission models with PKs 46 and 47.

---

### Control characters

If the content to be serialized contains control characters that are not accepted in the XML 1.0 standard, the serialization will fail with a `ValueError` exception. Read also the W3C's explanation of [HTML](#), [XHTML](#), [XML](#) and [Control Codes](#).

---

## JSON

When staying with the same example data as before it would be serialized as JSON in the following way:

```
[
  {
    "pk": "4b678b301dfd8a4e0dad910de3ae245b",
    "model": "sessions.session",
    "fields": {
      "expire_date": "2013-01-16T08:16:59.844Z",
      ...
    }
  }
]
```

The formatting here is a bit simpler than with XML. The whole collection is just represented as an array and the objects are represented by JSON objects with three properties: “pk”, “model” and “fields”. “fields” is again an object containing each field’s name and value as property and property-value respectively.

Foreign keys just have the PK of the linked object as property value. ManyToMany-relations are serialized for the model that defines them and are represented as a list of PKs.

Be aware that not all Django output can be passed unmodified to `json`. For example, if you have some custom type in an object to be serialized, you’ll have to write a custom `json` encoder for it. Something like this will work:

```
from django.utils.encoding import force_text
from django.core.serializers.json import DjangoJSONEncoder

class LazyEncoder(DjangoJSONEncoder):
    def default(self, obj):
        if isinstance(obj, YourCustomType):
            return force_text(obj)
        return super(LazyEncoder, self).default(obj)
```

Also note that GeoDjango provides a *customized GeoJSON serializer*.

### DjangoJSONEncoder

```
class django.core.serializers.json.DjangoJSONEncoder
```

The JSON serializer uses `DjangoJSONEncoder` for encoding. A subclass of `JSONEncoder`, it handles these additional types:

**datetime** A string of the form `YYYY-MM-DDTHH:mm:ss.sssZ` or `YYYY-MM-DDTHH:mm:ss.sss+HH:MM` as defined in [ECMA-262](#).

**date** A string of the form `YYYY-MM-DD` as defined in [ECMA-262](#).

**time** A string of the form `HH:MM:ss.sss` as defined in [ECMA-262](#).

**Decimal, Promise (django.utils.functional.lazy() objects), UUID** A string representation of the object.

Support for `Promise` was added.

## YAML

YAML serialization looks quite similar to JSON. The object list is serialized as a sequence mappings with the keys “pk”, “model” and “fields”. Each field is again a mapping with the key being name of the field and the value the value:

```
- fields: {expire_date: !!timestamp '2013-01-16 08:16:59.844560+00:00'}
  model: sessions.session
  pk: 4b678b301dfd8a4e0dad910de3ae245b
```

Referential fields are again just represented by the PK or sequence of PKs.

### 3.21.4 Natural keys

The default serialization strategy for foreign keys and many-to-many relations is to serialize the value of the primary key(s) of the objects in the relation. This strategy works well for most objects, but it can cause difficulty in some circumstances.

Consider the case of a list of objects that have a foreign key referencing `ContentType`. If you’re going to serialize an object that refers to a content type, then you need to have a way to refer to that content type to begin with. Since `ContentType` objects are automatically created by Django during the database synchronization process, the primary key of a given content type isn’t easy to predict; it will depend on how and when `migrate` was executed. This is true for all models which automatically generate objects, notably including `Permission`, `Group`, and `User`.

**Warning:** You should never include automatically generated objects in a fixture or other serialized data. By chance, the primary keys in the fixture may match those in the database and loading the fixture will have no effect. In the more likely case that they don’t match, the fixture loading will fail with an `IntegrityError`.

There is also the matter of convenience. An integer id isn’t always the most convenient way to refer to an object; sometimes, a more natural reference would be helpful.

It is for these reasons that Django provides *natural keys*. A natural key is a tuple of values that can be used to uniquely identify an object instance without using the primary key value.

### Deserialization of natural keys

Consider the following two models:

```
from django.db import models

class Person(models.Model):
    first_name = models.CharField(max_length=100)
    last_name = models.CharField(max_length=100)
```

```
birthdate = models.DateField()

class Meta:
    unique_together = (('first_name', 'last_name'),)

class Book(models.Model):
    name = models.CharField(max_length=100)
    author = models.ForeignKey(Person, on_delete=models.CASCADE)
```

Ordinarily, serialized data for `Book` would use an integer to refer to the author. For example, in JSON, a `Book` might be serialized as:

```
...
{
    "pk": 1,
    "model": "store.book",
    "fields": {
        "name": "Mostly Harmless",
        "author": 42
    }
}
...
```

This isn't a particularly natural way to refer to an author. It requires that you know the primary key value for the author; it also requires that this primary key value is stable and predictable.

However, if we add natural key handling to `Person`, the fixture becomes much more humane. To add natural key handling, you define a default `Manager` for `Person` with a `get_by_natural_key()` method. In the case of a `Person`, a good natural key might be the pair of first and last name:

```
from django.db import models

class PersonManager(models.Manager):
    def get_by_natural_key(self, first_name, last_name):
        return self.get(first_name=first_name, last_name=last_name)

class Person(models.Model):
    objects = PersonManager()

    first_name = models.CharField(max_length=100)
    last_name = models.CharField(max_length=100)

    birthdate = models.DateField()

    class Meta:
        unique_together = (('first_name', 'last_name'),)
```

Now books can use that natural key to refer to `Person` objects:

```
...
{
    "pk": 1,
    "model": "store.book",
    "fields": {
        "name": "Mostly Harmless",
        "author": ["Douglas", "Adams"]
    }
}
```

```
}
...
```

When you try to load this serialized data, Django will use the `get_by_natural_key()` method to resolve `["Douglas", "Adams"]` into the primary key of an actual `Person` object.

**Note:** Whatever fields you use for a natural key must be able to uniquely identify an object. This will usually mean that your model will have a uniqueness clause (either `unique=True` on a single field, or `unique_together` over multiple fields) for the field or fields in your natural key. However, uniqueness doesn't need to be enforced at the database level. If you are certain that a set of fields will be effectively unique, you can still use those fields as a natural key.

Deserialization of objects with no primary key will always check whether the model's manager has a `get_by_natural_key()` method and if so, use it to populate the deserialized object's primary key.

### Serialization of natural keys

So how do you get Django to emit a natural key when serializing an object? Firstly, you need to add another method – this time to the model itself:

```
class Person(models.Model):
    objects = PersonManager()

    first_name = models.CharField(max_length=100)
    last_name = models.CharField(max_length=100)

    birthdate = models.DateField()

    def natural_key(self):
        return (self.first_name, self.last_name)

    class Meta:
        unique_together = (('first_name', 'last_name'),)
```

That method should always return a natural key tuple – in this example, `(first name, last name)`. Then, when you call `serializers.serialize()`, you provide `use_natural_foreign_keys=True` or `use_natural_primary_keys=True` arguments:

```
>>> serializers.serialize('json', [book1, book2], indent=2,
...     use_natural_foreign_keys=True, use_natural_primary_keys=True)
```

When `use_natural_foreign_keys=True` is specified, Django will use the `natural_key()` method to serialize any foreign key reference to objects of the type that defines the method.

When `use_natural_primary_keys=True` is specified, Django will not provide the primary key in the serialized data of this object since it can be calculated during deserialization:

```
...
{
  "model": "store.person",
  "fields": {
    "first_name": "Douglas",
    "last_name": "Adams",
    "birth_date": "1952-03-11",
  }
}
```

```
}  
...
```

This can be useful when you need to load serialized data into an existing database and you cannot guarantee that the serialized primary key value is not already in use, and do not need to ensure that deserialized objects retain the same primary keys.

If you are using `dumpdata` to generate serialized data, use the `dumpdata --natural-foreign` and `dumpdata --natural-primary` command line flags to generate natural keys.

---

**Note:** You don't need to define both `natural_key()` and `get_by_natural_key()`. If you don't want Django to output natural keys during serialization, but you want to retain the ability to load natural keys, then you can opt to not implement the `natural_key()` method.

Conversely, if (for some strange reason) you want Django to output natural keys during serialization, but *not* be able to load those key values, just don't define the `get_by_natural_key()` method.

---

## Dependencies during serialization

Since natural keys rely on database lookups to resolve references, it is important that the data exists before it is referenced. You can't make a "forward reference" with natural keys – the data you're referencing must exist before you include a natural key reference to that data.

To accommodate this limitation, calls to `dumpdata` that use the `dumpdata --natural-foreign` option will serialize any model with a `natural_key()` method before serializing standard primary key objects.

However, this may not always be enough. If your natural key refers to another object (by using a foreign key or natural key to another object as part of a natural key), then you need to be able to ensure that the objects on which a natural key depends occur in the serialized data before the natural key requires them.

To control this ordering, you can define dependencies on your `natural_key()` methods. You do this by setting a `dependencies` attribute on the `natural_key()` method itself.

For example, let's add a natural key to the `Book` model from the example above:

```
class Book(models.Model):  
    name = models.CharField(max_length=100)  
    author = models.ForeignKey(Person, on_delete=models.CASCADE)  
  
    def natural_key(self):  
        return (self.name,) + self.author.natural_key()
```

The natural key for a `Book` is a combination of its name and its author. This means that `Person` must be serialized before `Book`. To define this dependency, we add one extra line:

```
def natural_key(self):  
    return (self.name,) + self.author.natural_key()  
natural_key.dependencies = ['example_app.person']
```

This definition ensures that all `Person` objects are serialized before any `Book` objects. In turn, any object referencing `Book` will be serialized after both `Person` and `Book` have been serialized.

## 3.22 Django settings

A Django settings file contains all the configuration of your Django installation. This document explains how settings work and which settings are available.

### 3.22.1 The basics

A settings file is just a Python module with module-level variables.

Here are a couple of example settings:

```
ALLOWED_HOSTS = ['www.example.com']
DEBUG = False
DEFAULT_FROM_EMAIL = 'webmaster@example.com'
```

**Note:** If you set `DEBUG` to `False`, you also need to properly set the `ALLOWED_HOSTS` setting.

Because a settings file is a Python module, the following apply:

- It doesn't allow for Python syntax errors.
- It can assign settings dynamically using normal Python syntax. For example:

```
MY_SETTING = [str(i) for i in range(30)]
```

- It can import values from other settings files.

### 3.22.2 Designating the settings

#### DJANGO\_SETTINGS\_MODULE

When you use Django, you have to tell it which settings you're using. Do this by using an environment variable, `DJANGO_SETTINGS_MODULE`.

The value of `DJANGO_SETTINGS_MODULE` should be in Python path syntax, e.g. `mysite.settings`. Note that the settings module should be on the Python [import search path](#).

#### The `django-admin` utility

When using `django-admin`, you can either set the environment variable once, or explicitly pass in the settings module each time you run the utility.

Example (Unix Bash shell):

```
export DJANGO_SETTINGS_MODULE=mysite.settings
django-admin runserver
```

Example (Windows shell):

```
set DJANGO_SETTINGS_MODULE=mysite.settings
django-admin runserver
```

Use the `--settings` command-line argument to specify the settings manually:

```
django-admin runserver --settings=mysite.settings
```

### On the server (`mod_wsgi`)

In your live server environment, you'll need to tell your WSGI application what settings file to use. Do that with `os.environ`:

```
import os

os.environ['DJANGO_SETTINGS_MODULE'] = 'mysite.settings'
```

Read the *Django mod\_wsgi documentation* for more information and other common elements to a Django WSGI application.

## 3.22.3 Default settings

A Django settings file doesn't have to define any settings if it doesn't need to. Each setting has a sensible default value. These defaults live in the module `django/conf/global_settings.py`.

Here's the algorithm Django uses in compiling settings:

- Load settings from `global_settings.py`.
- Load settings from the specified settings file, overriding the global settings as necessary.

Note that a settings file should *not* import from `global_settings`, because that's redundant.

### Seeing which settings you've changed

There's an easy way to view which of your settings deviate from the default settings. The command `python manage.py diffsettings` displays differences between the current settings file and Django's default settings.

For more, see the *diffsettings* documentation.

## 3.22.4 Using settings in Python code

In your Django apps, use settings by importing the object `django.conf.settings`. Example:

```
from django.conf import settings

if settings.DEBUG:
    # Do something
```

Note that `django.conf.settings` isn't a module – it's an object. So importing individual settings is not possible:

```
from django.conf.settings import DEBUG # This won't work.
```

Also note that your code should *not* import from either `global_settings` or your own settings file. `django.conf.settings` abstracts the concepts of default settings and site-specific settings; it presents a single interface. It also decouples the code that uses settings from the location of your settings.

### 3.22.5 Altering settings at runtime

You shouldn't alter settings in your applications at runtime. For example, don't do this in a view:

```
from django.conf import settings

settings.DEBUG = True    # Don't do this!
```

The only place you should assign to settings is in a settings file.

### 3.22.6 Security

Because a settings file contains sensitive information, such as the database password, you should make every attempt to limit access to it. For example, change its file permissions so that only you and your Web server's user can read it. This is especially important in a shared-hosting environment.

### 3.22.7 Available settings

For a full list of available settings, see the *settings reference*.

### 3.22.8 Creating your own settings

There's nothing stopping you from creating your own settings, for your own Django apps. Just follow these guidelines:

- Setting names must be all uppercase.
- Don't reinvent an already-existing setting.

For settings that are sequences, Django itself uses lists, but this is only a convention.

### 3.22.9 Using settings without setting `DJANGO_SETTINGS_MODULE`

In some cases, you might want to bypass the `DJANGO_SETTINGS_MODULE` environment variable. For example, if you're using the template system by itself, you likely don't want to have to set up an environment variable pointing to a settings module.

In these cases, you can configure Django's settings manually. Do this by calling:

```
django.conf.settings.configure(default_settings, **settings)
```

Example:

```
from django.conf import settings

settings.configure(DEBUG=True)
```

Pass `configure()` as many keyword arguments as you'd like, with each keyword argument representing a setting and its value. Each argument name should be all uppercase, with the same name as the settings described above. If a particular setting is not passed to `configure()` and is needed at some later point, Django will use the default setting value.

Configuring Django in this fashion is mostly necessary – and, indeed, recommended – when you're using a piece of the framework inside a larger application.

Consequently, when configured via `settings.configure()`, Django will not make any modifications to the process environment variables (see the documentation of `TIME_ZONE` for why this would normally occur). It's assumed that you're already in full control of your environment in these cases.

### Custom default settings

If you'd like default values to come from somewhere other than `django.conf.global_settings`, you can pass in a module or class that provides the default settings as the `default_settings` argument (or as the first positional argument) in the call to `configure()`.

In this example, default settings are taken from `myapp_defaults`, and the `DEBUG` setting is set to `True`, regardless of its value in `myapp_defaults`:

```
from django.conf import settings
from myapp import myapp_defaults

settings.configure(default_settings=myapp_defaults, DEBUG=True)
```

The following example, which uses `myapp_defaults` as a positional argument, is equivalent:

```
settings.configure(myapp_defaults, DEBUG=True)
```

Normally, you will not need to override the defaults in this fashion. The Django defaults are sufficiently tame that you can safely use them. Be aware that if you do pass in a new default module, it entirely *replaces* the Django defaults, so you must specify a value for every possible setting that might be used in that code you are importing. Check in `django.conf.settings.global_settings` for the full list.

### Either `configure()` or `DJANGO_SETTINGS_MODULE` is required

If you're not setting the `DJANGO_SETTINGS_MODULE` environment variable, you *must* call `configure()` at some point before using any code that reads settings.

If you don't set `DJANGO_SETTINGS_MODULE` and don't call `configure()`, Django will raise an `ImportError` exception the first time a setting is accessed.

If you set `DJANGO_SETTINGS_MODULE`, access settings values somehow, *then* call `configure()`, Django will raise a `RuntimeError` indicating that settings have already been configured. There is a property just for this purpose:

For example:

```
from django.conf import settings
if not settings.configured:
    settings.configure(myapp_defaults, DEBUG=True)
```

Also, it's an error to call `configure()` more than once, or to call `configure()` after any setting has been accessed.

It boils down to this: Use exactly one of either `configure()` or `DJANGO_SETTINGS_MODULE`. Not both, and not neither.

### Calling `django.setup()` is required for “standalone” Django usage

If you're using components of Django “standalone” – for example, writing a Python script which loads some Django templates and renders them, or uses the ORM to fetch some data – there's one more step you'll need in addition to configuring settings.

After you've either set `DJANGO_SETTINGS_MODULE` or called `configure()`, you'll need to call `django.setup()` to load your settings and populate Django's application registry. For example:

```
import django
from django.conf import settings
from myapp import myapp_defaults

settings.configure(default_settings=myapp_defaults, DEBUG=True)
django.setup()

# Now this script or any imported module can use any part of Django it needs.
from myapp import models
```

Note that calling `django.setup()` is only necessary if your code is truly standalone. When invoked by your Web server, or through *django-admin*, Django will handle this for you.

---

**django.setup()** may only be called once.

Therefore, avoid putting reusable application logic in standalone scripts so that you have to import from the script elsewhere in your application. If you can't avoid that, put the call to `django.setup()` inside an `if` block:

```
if __name__ == '__main__':
    import django
    django.setup()
```

---

*The Settings Reference* Contains the complete list of core and contrib app settings.

## 3.23 Signals

Django includes a “signal dispatcher” which helps allow decoupled applications get notified when actions occur elsewhere in the framework. In a nutshell, signals allow certain *senders* to notify a set of *receivers* that some action has taken place. They're especially useful when many pieces of code may be interested in the same events.

Django provides a *set of built-in signals* that let user code get notified by Django itself of certain actions. These include some useful notifications:

- `django.db.models.signals.pre_save` & `django.db.models.signals.post_save`  
Sent before or after a model's `save()` method is called.
- `django.db.models.signals.pre_delete` & `django.db.models.signals.post_delete`  
Sent before or after a model's `delete()` method or queryset's `delete()` method is called.
- `django.db.models.signals.m2m_changed`  
Sent when a `ManyToManyField` on a model is changed.
- `django.core.signals.request_started` & `django.core.signals.request_finished`  
Sent when Django starts or finishes an HTTP request.

See the *built-in signal documentation* for a complete list, and a complete explanation of each signal.

You can also *define and send your own custom signals*; see below.

### 3.23.1 Listening to signals

To receive a signal, register a *receiver* function using the `Signal.connect()` method. The receiver function is called when the signal is sent.

`Signal.connect(receiver, sender=None, weak=True, dispatch_uid=None)`

#### Parameters

- **receiver** – The callback function which will be connected to this signal. See *Receiver functions* for more information.
- **sender** – Specifies a particular sender to receive signals from. See *Connecting to signals sent by specific senders* for more information.
- **weak** – Django stores signal handlers as weak references by default. Thus, if your receiver is a local function, it may be garbage collected. To prevent this, pass `weak=False` when you call the signal's `connect()` method.
- **dispatch\_uid** – A unique identifier for a signal receiver in cases where duplicate signals may be sent. See *Preventing duplicate signals* for more information.

Let's see how this works by registering a signal that gets called after each HTTP request is finished. We'll be connecting to the `request_finished` signal.

#### Receiver functions

First, we need to define a receiver function. A receiver can be any Python function or method:

```
def my_callback(sender, **kwargs):  
    print("Request finished!")
```

Notice that the function takes a `sender` argument, along with wildcard keyword arguments (`**kwargs`); all signal handlers must take these arguments.

We'll look at senders *a bit later*, but right now look at the `**kwargs` argument. All signals send keyword arguments, and may change those keyword arguments at any time. In the case of `request_finished`, it's documented as sending no arguments, which means we might be tempted to write our signal handling as `my_callback(sender)`.

This would be wrong – in fact, Django will throw an error if you do so. That's because at any point arguments could get added to the signal and your receiver must be able to handle those new arguments.

#### Connecting receiver functions

There are two ways you can connect a receiver to a signal. You can take the manual connect route:

```
from django.core.signals import request_finished  
  
request_finished.connect(my_callback)
```

Alternatively, you can use a `receiver()` decorator:

```
receiver(signal)
```

**Parameters** `signal` – A signal or a list of signals to connect a function to.

Here's how you connect with the decorator:

```
from django.core.signals import request_finished
from django.dispatch import receiver

@receiver(request_finished)
def my_callback(sender, **kwargs):
    print("Request finished!")
```

Now, our `my_callback` function will be called each time a request finishes.

---

### Where should this code live?

Strictly speaking, signal handling and registration code can live anywhere you like, although it's recommended to avoid the application's root module and its `models` module to minimize side-effects of importing code.

In practice, signal handlers are usually defined in a `signals` submodule of the application they relate to. Signal receivers are connected in the `ready()` method of your application configuration class. If you're using the `receiver()` decorator, simply import the `signals` submodule inside `ready()`.

---

**Note:** The `ready()` method may be executed more than once during testing, so you may want to *guard your signals from duplication*, especially if you're planning to send them within tests.

---

### Connecting to signals sent by specific senders

Some signals get sent many times, but you'll only be interested in receiving a certain subset of those signals. For example, consider the `django.db.models.signals.pre_save` signal sent before a model gets saved. Most of the time, you don't need to know when *any* model gets saved – just when one *specific* model is saved.

In these cases, you can register to receive signals sent only by particular senders. In the case of `django.db.models.signals.pre_save`, the sender will be the model class being saved, so you can indicate that you only want signals sent by some model:

```
from django.db.models.signals import pre_save
from django.dispatch import receiver
from myapp.models import MyModel

@receiver(pre_save, sender=MyModel)
def my_handler(sender, **kwargs):
    ...
```

The `my_handler` function will only be called when an instance of `MyModel` is saved.

Different signals use different objects as their senders; you'll need to consult the *built-in signal documentation* for details of each particular signal.

### Preventing duplicate signals

In some circumstances, the code connecting receivers to signals may run multiple times. This can cause your receiver function to be registered more than once, and thus called multiple times for a single signal event.

If this behavior is problematic (such as when using signals to send an email whenever a model is saved), pass a unique identifier as the `dispatch_uid` argument to identify your receiver function. This identifier will usually be a string,

although any hashable object will suffice. The end result is that your receiver function will only be bound to the signal once for each unique `dispatch_uid` value:

```
from django.core.signals import request_finished

request_finished.connect(my_callback, dispatch_uid="my_unique_identifier")
```

### 3.23.2 Defining and sending signals

Your applications can take advantage of the signal infrastructure and provide its own signals.

#### Defining signals

**class** `Signal` (*providing\_args=list*)

All signals are `django.dispatch.Signal` instances. The `providing_args` is a list of the names of arguments the signal will provide to listeners. This is purely documentary, however, as there is nothing that checks that the signal actually provides these arguments to its listeners.

For example:

```
import django.dispatch

pizza_done = django.dispatch.Signal(providing_args=["toppings", "size"])
```

This declares a `pizza_done` signal that will provide receivers with `toppings` and `size` arguments.

Remember that you're allowed to change this list of arguments at any time, so getting the API right on the first try isn't necessary.

#### Sending signals

There are two ways to send signals in Django.

`Signal.send(sender, **kwargs)`

`Signal.send_robust(sender, **kwargs)`

To send a signal, call either `Signal.send()` (all built-in signals use this) or `Signal.send_robust()`. You must provide the `sender` argument (which is a class most of the time) and may provide as many other keyword arguments as you like.

For example, here's how sending our `pizza_done` signal might look:

```
class PizzaStore(object):
    ...

    def send_pizza(self, toppings, size):
        pizza_done.send(sender=self.__class__, toppings=toppings, size=size)
    ...
```

Both `send()` and `send_robust()` return a list of tuple pairs `[(receiver, response), ...]`, representing the list of called receiver functions and their response values.

`send()` differs from `send_robust()` in how exceptions raised by receiver functions are handled. `send()` does *not* catch any exceptions raised by receivers; it simply allows errors to propagate. Thus not all receivers may be notified of a signal in the face of an error.

`send_robust()` catches all errors derived from Python's `Exception` class, and ensures all receivers are notified of the signal. If an error occurs, the error instance is returned in the tuple pair for the receiver that raised the error.

The tracebacks are present on the `__traceback__` attribute of the errors returned when calling `send_robust()`.

### 3.23.3 Disconnecting signals

`Signal.disconnect` (*receiver=None, sender=None, dispatch\_uid=None*)

To disconnect a receiver from a signal, call `Signal.disconnect()`. The arguments are as described in `Signal.connect()`. The method returns `True` if a receiver was disconnected and `False` if not.

The `receiver` argument indicates the registered receiver to disconnect. It may be `None` if `dispatch_uid` is used to identify the receiver.

Deprecated since version 1.9: The `weak` argument is deprecated as it has no effect. It will be removed in Django 2.0.

## 3.24 System check framework

The system check framework is a set of static checks for validating Django projects. It detects common problems and provides hints for how to fix them. The framework is extensible so you can easily add your own checks.

Checks can be triggered explicitly via the `check` command. Checks are triggered implicitly before most commands, including `runserver` and `migrate`. For performance reasons, checks are not run as part of the WSGI stack that is used in deployment. If you need to run system checks on your deployment server, trigger them explicitly using `check`.

Serious errors will prevent Django commands (such as `runserver`) from running at all. Minor problems are reported to the console. If you have inspected the cause of a warning and are happy to ignore it, you can hide specific warnings using the `SILENCED_SYSTEM_CHECKS` setting in your project settings file.

A full list of all checks that can be raised by Django can be found in the [System check reference](#).

### 3.24.1 Writing your own checks

The framework is flexible and allows you to write functions that perform any other kind of check you may require. The following is an example stub check function:

```
from django.core.checks import Error, register

@register()
def example_check(app_configs, **kwargs):
    errors = []
    # ... your check logic here
    if check_failed:
        errors.append(
            Error(
                'an error',
                hint='A hint.',
                obj=checked_object,
                id='myapp.E001',
            )
        )
    return errors
```

The check function *must* accept an `app_configs` argument; this argument is the list of applications that should be inspected. If `None`, the check must be run on *all* installed apps in the project. The `**kwargs` argument is required for future expansion.

## Messages

The function must return a list of messages. If no problems are found as a result of the check, the check function must return an empty list.

The warnings and errors raised by the check method must be instances of `CheckMessage`. An instance of `CheckMessage` encapsulates a single reportable error or warning. It also provides context and hints applicable to the message, and a unique identifier that is used for filtering purposes.

The concept is very similar to messages from the *message framework* or the *logging framework*. Messages are tagged with a `level` indicating the severity of the message.

There are also shortcuts to make creating messages with common levels easier. When using these classes you can omit the `level` argument because it is implied by the class name.

- `Debug`
- `Info`
- `Warning`
- `Error`
- `Critical`

## Registering and labeling checks

Lastly, your check function must be registered explicitly with system check registry. Checks should be registered in a file that's loaded when your application is loaded; for example, in the `AppConfig.ready()` method.

**register** (\*tags)(function)

You can pass as many tags to `register` as you want in order to label your check. Tagging checks is useful since it allows you to run only a certain group of checks. For example, to register a compatibility check, you would make the following call:

```
from django.core.checks import register, Tags

@register(Tags.compatibility)
def my_check(app_configs, **kwargs):
    # ... perform compatibility checks and collect errors
    return errors
```

You can register “deployment checks” that are only relevant to a production settings file like this:

```
@register(Tags.security, deploy=True)
def my_check(app_configs, **kwargs):
    ...
```

These checks will only be run if the `check --deploy` option is used.

You can also use `register` as a function rather than a decorator by passing a callable object (usually a function) as the first argument to `register`.

The code below is equivalent to the code above:

```
def my_check(app_configs, **kwargs):
    ...
register(my_check, Tags.security, deploy=True)
```

## Field, model, manager, and database checks

In some cases, you won't need to register your check function – you can piggyback on an existing registration.

Fields, models, model managers, and database backends all implement a `check()` method that is already registered with the check framework. If you want to add extra checks, you can extend the implementation on the base class, perform any extra checks you need, and append any messages to those generated by the base class. It's recommended that you delegate each check to separate methods.

Database backend checks were added.

Consider an example where you are implementing a custom field named `RangedIntegerField`. This field adds `min` and `max` arguments to the constructor of `IntegerField`. You may want to add a check to ensure that users provide a `min` value that is less than or equal to the `max` value. The following code snippet shows how you can implement this check:

```
from django.core import checks
from django.db import models

class RangedIntegerField(models.IntegerField):
    def __init__(self, min=None, max=None, **kwargs):
        super(RangedIntegerField, self).__init__(**kwargs)
        self.min = min
        self.max = max

    def check(self, **kwargs):
        # Call the superclass
        errors = super(RangedIntegerField, self).check(**kwargs)

        # Do some custom checks and add messages to `errors`:
        errors.extend(self._check_min_max_values(**kwargs))

        # Return all errors and warnings
        return errors

    def _check_min_max_values(self, **kwargs):
        if (self.min is not None and
            self.max is not None and
            self.min > self.max):
            return [
                checks.Error(
                    'min greater than max.',
                    hint='Decrease min or increase max.',
                    obj=self,
                    id='myapp.E001',
                )
            ]
        # When no error, return an empty list
        return []
```

If you wanted to add checks to a model manager, you would take the same approach on your subclass of `Manager`.

If you want to add a check to a model class, the approach is *almost* the same: the only difference is that the check is a

classmethod, not an instance method:

```
class MyModel(models.Model):
    @classmethod
    def check(cls, **kwargs):
        errors = super(MyModel, cls).check(**kwargs)
        # ... your own checks ...
        return errors
```

## Writing tests

Messages are comparable. That allows you to easily write tests:

```
from django.core.checks import Error
errors = checked_object.check()
expected_errors = [
    Error(
        'an error',
        hint='A hint.',
        obj=checked_object,
        id='myapp.E001',
    )
]
self.assertEqual(errors, expected_errors)
```

## 3.25 External packages

Django ships with a variety of extra, optional tools that solve common problems (`contrib.*`). For easier maintenance and to trim the size of the codebase, a few of those applications have been moved out to separate projects.

### 3.25.1 Localflavor

`django-localflavor` is a collection of utilities for particular countries and cultures.

- [GitHub](#)
- [Documentation](#)
- [PyPI](#)

### 3.25.2 Comments

`django-contrib-comments` can be used to attach comments to any model, so you can use it for comments on blog entries, photos, book chapters, or anything else. Most users will be better served with a custom solution, or a hosted product like Disqus.

- [GitHub](#)
- [Documentation](#)
- [PyPI](#)

### 3.25.3 Formtools

`django-formtools` is a collection of assorted utilities to work with forms.

- [GitHub](#)
- [Documentation](#)
- [PyPI](#)

Here you’ll find short answers to “How do I...?” types of questions. These how-to guides don’t cover topics in depth – you’ll find that material in the *Using Django* and the *API Reference*. However, these guides will help you quickly accomplish common tasks.

## 4.1 Authentication using REMOTE\_USER

This document describes how to make use of external authentication sources (where the Web server sets the REMOTE\_USER environment variable) in your Django applications. This type of authentication solution is typically seen on intranet sites, with single sign-on solutions such as IIS and Integrated Windows Authentication or Apache and `mod_authnz_ldap`, `CAS`, `Cosign`, `WebAuth`, `mod_auth_sspi`, etc.

When the Web server takes care of authentication it typically sets the REMOTE\_USER environment variable for use in the underlying application. In Django, REMOTE\_USER is made available in the `request.META` attribute. Django can be configured to make use of the REMOTE\_USER value using the `RemoteUserMiddleware` or `PersistentRemoteUserMiddleware`, and `RemoteUserBackend` classes found in `django.contrib.auth`.

### 4.1.1 Configuration

First, you must add the `django.contrib.auth.middleware.RemoteUserMiddleware` to the `MIDDLEWARE` setting **after** the `django.contrib.auth.middleware.AuthenticationMiddleware`:

```
MIDDLEWARE = [  
    '...',  
    'django.contrib.auth.middleware.AuthenticationMiddleware',  
    'django.contrib.auth.middleware.RemoteUserMiddleware',  
    '...',  
]
```

Next, you must replace the `ModelBackend` with `RemoteUserBackend` in the `AUTHENTICATION_BACKENDS` setting:

```
AUTHENTICATION_BACKENDS = [  
    'django.contrib.auth.backends.RemoteUserBackend',  
]
```

With this setup, `RemoteUserMiddleware` will detect the username in `request.META['REMOTE_USER']` and will authenticate and auto-login that user using the `RemoteUserBackend`.

Be aware that this particular setup disables authentication with the default `ModelBackend`. This means that if the `REMOTE_USER` value is not set then the user is unable to log in, even using Django’s admin interface. Adding `'django.contrib.auth.backends.ModelBackend'` to the `AUTHENTICATION_BACKENDS` list will use `ModelBackend` as a fallback if `REMOTE_USER` is absent, which will solve these issues.

Django’s user management, such as the views in `contrib.admin` and the `createsuperuser` management command, doesn’t integrate with remote users. These interfaces work with users stored in the database regardless of `AUTHENTICATION_BACKENDS`.

---

**Note:** Since the `RemoteUserBackend` inherits from `ModelBackend`, you will still have all of the same permissions checking that is implemented in `ModelBackend`.

Users with `is_active=False` won’t be allowed to authenticate. Use `AllowAllUsersRemoteUserBackend` if you want to allow them to.

In older versions, inactive users weren’t rejected as described above.

---

If your authentication mechanism uses a custom HTTP header and not `REMOTE_USER`, you can subclass `RemoteUserMiddleware` and set the `header` attribute to the desired `request.META` key. For example:

```
from django.contrib.auth.middleware import RemoteUserMiddleware  
  
class CustomHeaderMiddleware(RemoteUserMiddleware):  
    header = 'HTTP_AUTHUSER'
```

**Warning:** Be very careful if using a `RemoteUserMiddleware` subclass with a custom HTTP header. You must be sure that your front-end web server always sets or strips that header based on the appropriate authentication checks, never permitting an end-user to submit a fake (or “spoofed”) header value. Since the HTTP headers `X-Auth-User` and `X-Auth_User` (for example) both normalize to the `HTTP_X_AUTH_USER` key in `request.META`, you must also check that your web server doesn’t allow a spoofed header using underscores in place of dashes.

This warning doesn’t apply to `RemoteUserMiddleware` in its default configuration with `header = 'REMOTE_USER'`, since a key that doesn’t start with `HTTP_` in `request.META` can only be set by your WSGI server, not directly from an HTTP request header.

If you need more control, you can create your own authentication backend that inherits from `RemoteUserBackend` and override one or more of its attributes and methods.

## 4.1.2 Using `REMOTE_USER` on login pages only

The `RemoteUserMiddleware` authentication middleware assumes that the HTTP request header `REMOTE_USER` is present with all authenticated requests. That might be expected and practical when Basic HTTP Auth with `htpasswd` or other simple mechanisms are used, but with Negotiate (GSSAPI/Kerberos) or other resource intensive authentication methods, the authentication in the front-end HTTP server is usually only set up for one or a few

login URLs, and after successful authentication, the application is supposed to maintain the authenticated session itself.

`PersistentRemoteUserMiddleware` provides support for this use case. It will maintain the authenticated session until explicit logout by the user. The class can be used as a drop-in replacement of `RemoteUserMiddleware` in the documentation above.

## 4.2 Writing custom django-admin commands

Applications can register their own actions with `manage.py`. For example, you might want to add a `manage.py` action for a Django app that you're distributing. In this document, we will be building a custom `closepoll` command for the `polls` application from the *tutorial*.

To do this, just add a `management/commands` directory to the application. Django will register a `manage.py` command for each Python module in that directory whose name doesn't begin with an underscore. For example:

```
polls/
  __init__.py
  models.py
  management/
    __init__.py
    commands/
      __init__.py
      _private.py
      closepoll.py
  tests.py
  views.py
```

On Python 2, be sure to include `__init__.py` files in both the `management` and `management/commands` directories as done above or your command will not be detected.

In this example, the `closepoll` command will be made available to any project that includes the `polls` application in `INSTALLED_APPS`.

The `_private.py` module will not be available as a management command.

The `closepoll.py` module has only one requirement – it must define a class `Command` that extends `BaseCommand` or one of its *subclasses*.

---

### Standalone scripts

Custom management commands are especially useful for running standalone scripts or for scripts that are periodically executed from the UNIX crontab or from Windows scheduled tasks control panel.

To implement the command, edit `polls/management/commands/closepoll.py` to look like this:

```
from django.core.management.base import BaseCommand, CommandError
from polls.models import Question as Poll

class Command(BaseCommand):
    help = 'Closes the specified poll for voting'

    def add_arguments(self, parser):
        parser.add_argument('poll_id', nargs='+', type=int)

    def handle(self, *args, **options):
```

```
for poll_id in options['poll_id']:
    try:
        poll = Poll.objects.get(pk=poll_id)
    except Poll.DoesNotExist:
        raise CommandError('Poll "%s" does not exist' % poll_id)

    poll.opened = False
    poll.save()

    self.stdout.write(self.style.SUCCESS('Successfully closed poll "%s"' %
↳poll_id))
```

**Note:** When you are using management commands and wish to provide console output, you should write to `self.stdout` and `self.stderr`, instead of printing to `stdout` and `stderr` directly. By using these proxies, it becomes much easier to test your custom command. Note also that you don't need to end messages with a newline character, it will be added automatically, unless you specify the ending parameter:

```
self.stdout.write("Unterminated line", ending='')
```

The new custom command can be called using `python manage.py closepoll <poll_id>`.

The `handle()` method takes one or more `poll_ids` and sets `poll.opened` to `False` for each one. If the user referenced any nonexistent polls, a `CommandError` is raised. The `poll.opened` attribute does not exist in the *tutorial* and was added to `polls.models.Question` for this example.

## 4.2.1 Accepting optional arguments

The same `closepoll` could be easily modified to delete a given poll instead of closing it by accepting additional command line options. These custom options can be added in the `add_arguments()` method like this:

```
class Command(BaseCommand):
    def add_arguments(self, parser):
        # Positional arguments
        parser.add_argument('poll_id', nargs='+', type=int)

        # Named (optional) arguments
        parser.add_argument(
            '--delete',
            action='store_true',
            dest='delete',
            default=False,
            help='Delete poll instead of closing it',
        )

    def handle(self, *args, **options):
        # ...
        if options['delete']:
            poll.delete()
        # ...
```

The option (`delete` in our example) is available in the options dict parameter of the `handle` method. See the `argparse` Python documentation for more about `add_argument` usage.

In addition to being able to add custom command line options, all *management commands* can accept some default options such as `--verbosity` and `--traceback`.

## 4.2.2 Management commands and locales

By default, the `BaseCommand.execute()` method deactivates translations because some commands shipped with Django perform several tasks (for example, user-facing content rendering and database population) that require a project-neutral string language.

If, for some reason, your custom management command needs to use a fixed locale, you should manually activate and deactivate it in your `handle()` method using the functions provided by the I18N support code:

```
from django.core.management.base import BaseCommand, CommandError
from django.utils import translation

class Command(BaseCommand):
    ...
    can_import_settings = True

    def handle(self, *args, **options):

        # Activate a fixed locale, e.g. Russian
        translation.activate('ru')

        # Or you can activate the LANGUAGE_CODE # chosen in the settings:
        from django.conf import settings
        translation.activate(settings.LANGUAGE_CODE)

        # Your command logic here
        ...

        translation.deactivate()
```

Another need might be that your command simply should use the locale set in settings and Django should be kept from deactivating it. You can achieve it by using the `BaseCommand.leave_locale_alone` option.

When working on the scenarios described above though, take into account that system management commands typically have to be very careful about running in non-uniform locales, so you might need to:

- Make sure the `USE_I18N` setting is always `True` when running the command (this is a good example of the potential problems stemming from a dynamic runtime environment that Django commands avoid offhand by deactivating translations).
- Review the code of your command and the code it calls for behavioral differences when locales are changed and evaluate its impact on predictable behavior of your command.

## 4.2.3 Testing

Information on how to test custom management commands can be found in the [testing docs](#).

## 4.2.4 Command objects

### class BaseCommand

The base class from which all management commands ultimately derive.

Use this class if you want access to all of the mechanisms which parse the command-line arguments and work out what code to call in response; if you don't need to change any of that behavior, consider using one of its [subclasses](#).

Subclassing the `BaseCommand` class requires that you implement the `handle()` method.

## Attributes

All attributes can be set in your derived class and can be used in *BaseCommand*'s subclasses.

### `BaseCommand.can_import_settings`

A boolean indicating whether the command needs to be able to import Django settings; if `True`, `execute()` will verify that this is possible before proceeding. Default value is `True`.

### `BaseCommand.help`

A short description of the command, which will be printed in the help message when the user runs the command `python manage.py help <command>`.

### `BaseCommand.missing_args_message`

If your command defines mandatory positional arguments, you can customize the message error returned in the case of missing arguments. The default is output by `argparse` (“too few arguments”).

### `BaseCommand.output_transaction`

A boolean indicating whether the command outputs SQL statements; if `True`, the output will automatically be wrapped with `BEGIN`; and `COMMIT`; . Default value is `False`.

### `BaseCommand.requires_migrations_checks`

A boolean; if `True`, the command prints a warning if the set of migrations on disk don't match the migrations in the database. A warning doesn't prevent the command from executing. Default value is `False`.

### `BaseCommand.requires_system_checks`

A boolean; if `True`, the entire Django project will be checked for potential problems prior to executing the command. Default value is `True`.

### `BaseCommand.leave_locale_alone`

A boolean indicating whether the locale set in settings should be preserved during the execution of the command instead of being forcibly set to 'en-us'.

Default value is `False`.

Make sure you know what you are doing if you decide to change the value of this option in your custom command if it creates database content that is locale-sensitive and such content shouldn't contain any translations (like it happens e.g. with `django.contrib.auth` permissions) as making the locale differ from the de facto default 'en-us' might cause unintended effects. See the *Management commands and locales* section above for further details.

This option can't be `False` when the `can_import_settings` option is set to `False` too because attempting to set the locale needs access to settings. This condition will generate a `CommandError`.

### `BaseCommand.style`

An instance attribute that helps create colored output when writing to `stdout` or `stderr`. For example:

```
self.stdout.write(self.style.SUCCESS('...'))
```

See *Syntax coloring* to learn how to modify the color palette and to see the available styles (use uppercased versions of the “roles” described in that section).

If you pass the `--no-color` option when running your command, all `self.style()` calls will return the original string uncolored.

## Methods

*BaseCommand* has a few methods that can be overridden but only the `handle()` method must be implemented.

---

## Implementing a constructor in a subclass

If you implement `__init__` in your subclass of `BaseCommand`, you must call `BaseCommand`'s `__init__`:

```
class Command(BaseCommand):
    def __init__(self, *args, **kwargs):
        super(Command, self).__init__(*args, **kwargs)
        # ...
```

---

`BaseCommand.add_arguments` (*parser*)

Entry point to add parser arguments to handle command line arguments passed to the command. Custom commands should override this method to add both positional and optional arguments accepted by the command. Calling `super()` is not needed when directly subclassing `BaseCommand`.

`BaseCommand.get_version` ()

Returns the Django version, which should be correct for all built-in Django commands. User-supplied commands can override this method to return their own version.

`BaseCommand.execute` (\*args, \*\*options)

Tries to execute this command, performing system checks if needed (as controlled by the `requires_system_checks` attribute). If the command raises a `CommandError`, it's intercepted and printed to stderr.

---

### Calling a management command in your code

`execute()` should not be called directly from your code to execute a command. Use `call_command()` instead.

---

`BaseCommand.handle` (\*args, \*\*options)

The actual logic of the command. Subclasses must implement this method.

It may return a Unicode string which will be printed to stdout (wrapped by `BEGIN`; and `COMMIT`; if `output_transaction` is True).

`BaseCommand.check` (*app\_configs=None, tags=None, display\_num\_errors=False*)

Uses the system check framework to inspect the entire Django project for potential problems. Serious problems are raised as a `CommandError`; warnings are output to stderr; minor notifications are output to stdout.

If `app_configs` and `tags` are both `None`, all system checks are performed. `tags` can be a list of check tags, like `compatibility` or `models`.

### BaseCommand subclasses

#### class AppCommand

A management command which takes one or more installed application labels as arguments, and does something with each of them.

Rather than implementing `handle()`, subclasses must implement `handle_app_config()`, which will be called once for each application.

`AppCommand.handle_app_config` (*app\_config, \*\*options*)

Perform the command's actions for `app_config`, which will be an `AppConfig` instance corresponding to an application label given on the command line.

#### class LabelCommand

A management command which takes one or more arbitrary arguments (labels) on the command line, and does something with each of them.

Rather than implementing `handle()`, subclasses must implement `handle_label()`, which will be called once for each label.

`LabelCommand.label`

A string describing the arbitrary arguments passed to the command. The string is used in the usage text and error messages of the command. Defaults to `'label'`.

`LabelCommand.handle_label(label, **options)`

Perform the command's actions for `label`, which will be the string as given on the command line.

## Command exceptions

### exception `CommandError`

Exception class indicating a problem while executing a management command.

If this exception is raised during the execution of a management command from a command line console, it will be caught and turned into a nicely-printed error message to the appropriate output stream (i.e., `stderr`); as a result, raising this exception (with a sensible description of the error) is the preferred way to indicate that something has gone wrong in the execution of a command.

If a management command is called from code through `call_command()`, it's up to you to catch the exception when needed.

## 4.3 Writing custom model fields

### 4.3.1 Introduction

The *model reference* documentation explains how to use Django's standard field classes – `CharField`, `DateField`, etc. For many purposes, those classes are all you'll need. Sometimes, though, the Django version won't meet your precise requirements, or you'll want to use a field that is entirely different from those shipped with Django.

Django's built-in field types don't cover every possible database column type – only the common types, such as `VARCHAR` and `INTEGER`. For more obscure column types, such as geographic polygons or even user-created types such as [PostgreSQL custom types](#), you can define your own `Field` subclasses.

Alternatively, you may have a complex Python object that can somehow be serialized to fit into a standard database column type. This is another case where a `Field` subclass will help you use your object with your models.

### Our example object

Creating custom fields requires a bit of attention to detail. To make things easier to follow, we'll use a consistent example throughout this document: wrapping a Python object representing the deal of cards in a hand of [Bridge](#). Don't worry, you don't have to know how to play Bridge to follow this example. You only need to know that 52 cards are dealt out equally to four players, who are traditionally called *north*, *east*, *south* and *west*. Our class looks something like this:

```
class Hand(object):
    """A hand of cards (bridge style)"""

    def __init__(self, north, east, south, west):
        # Input parameters are lists of cards ('Ah', '9s', etc.)
        self.north = north
        self.east = east
        self.south = south
```

```

self.west = west

# ... (other possibly useful methods omitted) ...

```

This is just an ordinary Python class, with nothing Django-specific about it. We'd like to be able to do things like this in our models (we assume the `hand` attribute on the model is an instance of `Hand`):

```

example = MyModel.objects.get(pk=1)
print(example.hand.north)

new_hand = Hand(north, east, south, west)
example.hand = new_hand
example.save()

```

We assign to and retrieve from the `hand` attribute in our model just like any other Python class. The trick is to tell Django how to handle saving and loading such an object.

In order to use the `Hand` class in our models, we **do not** have to change this class at all. This is ideal, because it means you can easily write model support for existing classes where you cannot change the source code.

---

**Note:** You might only be wanting to take advantage of custom database column types and deal with the data as standard Python types in your models; strings, or floats, for example. This case is similar to our `Hand` example and we'll note any differences as we go along.

---

## 4.3.2 Background theory

### Database storage

The simplest way to think of a model field is that it provides a way to take a normal Python object – string, boolean, `datetime`, or something more complex like `Hand` – and convert it to and from a format that is useful when dealing with the database (and serialization, but, as we'll see later, that falls out fairly naturally once you have the database side under control).

Fields in a model must somehow be converted to fit into an existing database column type. Different databases provide different sets of valid column types, but the rule is still the same: those are the only types you have to work with. Anything you want to store in the database must fit into one of those types.

Normally, you're either writing a Django field to match a particular database column type, or there's a fairly straightforward way to convert your data to, say, a string.

For our `Hand` example, we could convert the card data to a string of 104 characters by concatenating all the cards together in a pre-determined order – say, all the *north* cards first, then the *east*, *south* and *west* cards. So `Hand` objects can be saved to text or character columns in the database.

### What does a field class do?

All of Django's fields (and when we say *fields* in this document, we always mean model fields and not *form fields*) are subclasses of `django.db.models.Field`. Most of the information that Django records about a field is common to all fields – name, help text, uniqueness and so forth. Storing all that information is handled by `Field`. We'll get into the precise details of what `Field` can do later on; for now, suffice it to say that everything descends from `Field` and then customizes key pieces of the class behavior.

It's important to realize that a Django field class is not what is stored in your model attributes. The model attributes contain normal Python objects. The field classes you define in a model are actually stored in the `Meta` class when

the model class is created (the precise details of how this is done are unimportant here). This is because the field classes aren't necessary when you're just creating and modifying attributes. Instead, they provide the machinery for converting between the attribute value and what is stored in the database or sent to the *serializer*.

Keep this in mind when creating your own custom fields. The Django `Field` subclass you write provides the machinery for converting between your Python instances and the database/serializer values in various ways (there are differences between storing a value and using a value for lookups, for example). If this sounds a bit tricky, don't worry – it will become clearer in the examples below. Just remember that you will often end up creating two classes when you want a custom field:

- The first class is the Python object that your users will manipulate. They will assign it to the model attribute, they will read from it for displaying purposes, things like that. This is the `Hand` class in our example.
- The second class is the `Field` subclass. This is the class that knows how to convert your first class back and forth between its permanent storage form and the Python form.

### 4.3.3 Writing a field subclass

When planning your *Field* subclass, first give some thought to which existing *Field* class your new field is most similar to. Can you subclass an existing Django field and save yourself some work? If not, you should subclass the *Field* class, from which everything is descended.

Initializing your new field is a matter of separating out any arguments that are specific to your case from the common arguments and passing the latter to the `__init__()` method of *Field* (or your parent class).

In our example, we'll call our field `HandField`. (It's a good idea to call your *Field* subclass `<Something>Field`, so it's easily identifiable as a *Field* subclass.) It doesn't behave like any existing field, so we'll subclass directly from *Field*:

```
from django.db import models

class HandField(models.Field):

    description = "A hand of cards (bridge style)"

    def __init__(self, *args, **kwargs):
        kwargs['max_length'] = 104
        super(HandField, self).__init__(*args, **kwargs)
```

Our `HandField` accepts most of the standard field options (see the list below), but we ensure it has a fixed length, since it only needs to hold 52 card values plus their suits; 104 characters in total.

---

**Note:** Many of Django's model fields accept options that they don't do anything with. For example, you can pass both *editable* and *auto\_now* to a `django.db.models.DateField` and it will simply ignore the *editable* parameter (*auto\_now* being set implies *editable=False*). No error is raised in this case.

This behavior simplifies the field classes, because they don't need to check for options that aren't necessary. They just pass all the options to the parent class and then don't use them later on. It's up to you whether you want your fields to be more strict about the options they select, or to use the simpler, more permissive behavior of the current fields.

---

The `Field.__init__()` method takes the following parameters:

- *verbose\_name*
- *name*
- *primary\_key*

- `max_length`
- `unique`
- `blank`
- `null`
- `db_index`
- `rel`: Used for related fields (like `ForeignKey`). For advanced use only.
- `default`
- `editable`
- `serialize`: If `False`, the field will not be serialized when the model is passed to Django's `serializers`. Defaults to `True`.
- `unique_for_date`
- `unique_for_month`
- `unique_for_year`
- `choices`
- `help_text`
- `db_column`
- `db_tablespace`: Only for index creation, if the backend supports `tablespaces`. You can usually ignore this option.
- `auto_created`: `True` if the field was automatically created, as for the `OneToOneField` used by model inheritance. For advanced use only.

All of the options without an explanation in the above list have the same meaning they do for normal Django fields. See the [field documentation](#) for examples and details.

## Field deconstruction

The counterpoint to writing your `__init__()` method is writing the `deconstruct()` method. This method tells Django how to take an instance of your new field and reduce it to a serialized form - in particular, what arguments to pass to `__init__()` to re-create it.

If you haven't added any extra options on top of the field you inherited from, then there's no need to write a new `deconstruct()` method. If, however, you're changing the arguments passed in `__init__()` (like we are in `HandField`), you'll need to supplement the values being passed.

The contract of `deconstruct()` is simple; it returns a tuple of four items: the field's attribute name, the full import path of the field class, the positional arguments (as a list), and the keyword arguments (as a dict). Note this is different from the `deconstruct()` method *for custom classes* which returns a tuple of three things.

As a custom field author, you don't need to care about the first two values; the base `Field` class has all the code to work out the field's attribute name and import path. You do, however, have to care about the positional and keyword arguments, as these are likely the things you are changing.

For example, in our `HandField` class we're always forcibly setting `max_length` in `__init__()`. The `deconstruct()` method on the base `Field` class will see this and try to return it in the keyword arguments; thus, we can drop it from the keyword arguments for readability:

```
from django.db import models

class HandField(models.Field):

    def __init__(self, *args, **kwargs):
        kwargs['max_length'] = 104
        super(HandField, self).__init__(*args, **kwargs)

    def deconstruct(self):
        name, path, args, kwargs = super(HandField, self).deconstruct()
        del kwargs["max_length"]
        return name, path, args, kwargs
```

If you add a new keyword argument, you need to write code to put its value into `kwargs` yourself:

```
from django.db import models

class CommaSepField(models.Field):
    """Implements comma-separated storage of lists"""

    def __init__(self, separator=",", *args, **kwargs):
        self.separator = separator
        super(CommaSepField, self).__init__(*args, **kwargs)

    def deconstruct(self):
        name, path, args, kwargs = super(CommaSepField, self).deconstruct()
        # Only include kwarg if it's not the default
        if self.separator != ",":
            kwargs['separator'] = self.separator
        return name, path, args, kwargs
```

More complex examples are beyond the scope of this document, but remember - for any configuration of your `Field` instance, `deconstruct()` must return arguments that you can pass to `__init__` to reconstruct that state.

Pay extra attention if you set new default values for arguments in the `Field` superclass; you want to make sure they're always included, rather than disappearing if they take on the old default value.

In addition, try to avoid returning values as positional arguments; where possible, return values as keyword arguments for maximum future compatibility. Of course, if you change the names of things more often than their position in the constructor's argument list, you might prefer positional, but bear in mind that people will be reconstructing your field from the serialized version for quite a while (possibly years), depending how long your migrations live for.

You can see the results of deconstruction by looking in migrations that include the field, and you can test deconstruction in unit tests by just deconstructing and reconstructing the field:

```
name, path, args, kwargs = my_field_instance.deconstruct()
new_instance = MyField(*args, **kwargs)
self.assertEqual(my_field_instance.some_attribute, new_instance.some_attribute)
```

## Changing a custom field's base class

You can't change the base class of a custom field because Django won't detect the change and make a migration for it. For example, if you start with:

```
class CustomCharField(models.CharField):
    ...
```

and then decide that you want to use `TextField` instead, you can't change the subclass like this:

```
class CustomCharField(models.TextField):
    ...
```

Instead, you must create a new custom field class and update your models to reference it:

```
class CustomCharField(models.CharField):
    ...

class CustomTextField(models.TextField):
    ...
```

As discussed in *removing fields*, you must retain the original `CustomCharField` class as long as you have migrations that reference it.

### Documenting your custom field

As always, you should document your field type, so users will know what it is. In addition to providing a docstring for it, which is useful for developers, you can also allow users of the admin app to see a short description of the field type via the `django.contrib.admindocs` application. To do this simply provide descriptive text in a `description` class attribute of your custom field. In the above example, the description displayed by the `admindocs` application for a `HandField` will be 'A hand of cards (bridge style)'.

In the `django.contrib.admindocs` display, the field description is interpolated with `field.__dict__` which allows the description to incorporate arguments of the field. For example, the description for `CharField` is:

```
description = _("String (up to %(max_length)s)")
```

### Useful methods

Once you've created your `Field` subclass, you might consider overriding a few standard methods, depending on your field's behavior. The list of methods below is in approximately decreasing order of importance, so start from the top.

### Custom database types

Say you've created a PostgreSQL custom type called `mytype`. You can subclass `Field` and implement the `db_type()` method, like so:

```
from django.db import models

class MytypeField(models.Field):
    def db_type(self, connection):
        return 'mytype'
```

Once you have `MytypeField`, you can use it in any model, just like any other `Field` type:

```
class Person(models.Model):
    name = models.CharField(max_length=80)
    something_else = MytypeField()
```

If you aim to build a database-agnostic application, you should account for differences in database column types. For example, the date/time column type in PostgreSQL is called `timestamp`, while the same column in MySQL

is called `datetime`. The simplest way to handle this in a `db_type()` method is to check the `connection.settings_dict['ENGINE']` attribute.

For example:

```
class MyDateField(models.Field):
    def db_type(self, connection):
        if connection.settings_dict['ENGINE'] == 'django.db.backends.mysql':
            return 'datetime'
        else:
            return 'timestamp'
```

The `db_type()` and `rel_db_type()` methods are called by Django when the framework constructs the CREATE TABLE statements for your application – that is, when you first create your tables. The methods are also called when constructing a WHERE clause that includes the model field – that is, when you retrieve data using QuerySet methods like `get()`, `filter()`, and `exclude()` and have the model field as an argument. They are not called at any other time, so it can afford to execute slightly complex code, such as the `connection.settings_dict` check in the above example.

Some database column types accept parameters, such as `CHAR(25)`, where the parameter 25 represents the maximum column length. In cases like these, it's more flexible if the parameter is specified in the model rather than being hard-coded in the `db_type()` method. For example, it wouldn't make much sense to have a `CharMaxlength25Field`, shown here:

```
# This is a silly example of hard-coded parameters.
class CharMaxlength25Field(models.Field):
    def db_type(self, connection):
        return 'char(25)'

# In the model:
class MyModel(models.Model):
    # ...
    my_field = CharMaxlength25Field()
```

The better way of doing this would be to make the parameter specifiable at run time – i.e., when the class is instantiated. To do that, just implement `Field.__init__()`, like so:

```
# This is a much more flexible example.
class BetterCharField(models.Field):
    def __init__(self, max_length, *args, **kwargs):
        self.max_length = max_length
        super(BetterCharField, self).__init__(*args, **kwargs)

    def db_type(self, connection):
        return 'char(%s)' % self.max_length

# In the model:
class MyModel(models.Model):
    # ...
    my_field = BetterCharField(25)
```

Finally, if your column requires truly complex SQL setup, return `None` from `db_type()`. This will cause Django's SQL creation code to skip over this field. You are then responsible for creating the column in the right table in some other way, of course, but this gives you a way to tell Django to get out of the way.

The `rel_db_type()` method is called by fields such as `ForeignKey` and `OneToOneField` that point to another field to determine their database column data types. For example, if you have an `UnsignedAutoField`, you also need the foreign keys that point to that field to use the same data type:

```
# MySQL unsigned integer (range 0 to 4294967295).
class UnsignedAutoField(models.AutoField):
    def db_type(self, connection):
        return 'integer UNSIGNED AUTO_INCREMENT'

    def rel_db_type(self, connection):
        return 'integer UNSIGNED'
```

The `rel_db_type()` method was added.

## Converting values to Python objects

If your custom `Field` class deals with data structures that are more complex than strings, dates, integers, or floats, then you may need to override `from_db_value()` and `to_python()`.

If present for the field subclass, `from_db_value()` will be called in all circumstances when the data is loaded from the database, including in aggregates and `values()` calls.

`to_python()` is called by deserialization and during the `clean()` method used from forms.

As a general rule, `to_python()` should deal gracefully with any of the following arguments:

- An instance of the correct type (e.g., `Hand` in our ongoing example).
- A string
- `None` (if the field allows `null=True`)

In our `HandField` class, we're storing the data as a `VARCHAR` field in the database, so we need to be able to process strings and `None` in the `from_db_value()`. In `to_python()`, we need to also handle `Hand` instances:

```
import re

from django.core.exceptions import ValidationError
from django.db import models
from django.utils.translation import ugettext_lazy as _

def parse_hand(hand_string):
    """Takes a string of cards and splits into a full hand."""
    p1 = re.compile('{26}')
    p2 = re.compile('.')
    args = [p2.findall(x) for x in p1.findall(hand_string)]
    if len(args) != 4:
        raise ValidationError(_("Invalid input for a Hand instance"))
    return Hand(*args)

class HandField(models.Field):
    # ...

    def from_db_value(self, value, expression, connection, context):
        if value is None:
            return value
        return parse_hand(value)

    def to_python(self, value):
        if isinstance(value, Hand):
            return value

        if value is None:
```

```
        return value

    return parse_hand(value)
```

Notice that we always return a `Hand` instance from these methods. That's the Python object type we want to store in the model's attribute.

For `to_python()`, if anything goes wrong during value conversion, you should raise a `ValidationError` exception.

## Converting Python objects to query values

Since using a database requires conversion in both ways, if you override `to_python()` you also have to override `get_prep_value()` to convert Python objects back to query values.

For example:

```
class HandField(models.Field):
    # ...

    def get_prep_value(self, value):
        return ''.join([''.join(l) for l in (value.north,
            value.east, value.south, value.west)])
```

**Warning:** If your custom field uses the `CHAR`, `VARCHAR` or `TEXT` types for MySQL, you must make sure that `get_prep_value()` always returns a string type. MySQL performs flexible and unexpected matching when a query is performed on these types and the provided value is an integer, which can cause queries to include unexpected objects in their results. This problem cannot occur if you always return a string type from `get_prep_value()`.

## Converting query values to database values

Some data types (for example, dates) need to be in a specific format before they can be used by a database backend. `get_db_prep_value()` is the method where those conversions should be made. The specific connection that will be used for the query is passed as the `connection` parameter. This allows you to use backend-specific conversion logic if it is required.

For example, Django uses the following method for its `BinaryField`:

```
def get_db_prep_value(self, value, connection, prepared=False):
    value = super(BinaryField, self).get_db_prep_value(value, connection, prepared)
    if value is not None:
        return connection.Database.Binary(value)
    return value
```

In case your custom field needs a special conversion when being saved that is not the same as the conversion used for normal query parameters, you can override `get_db_prep_save()`.

## Preprocessing values before saving

If you want to preprocess the value just before saving, you can use `pre_save()`. For example, Django's `DateTimeField` uses this method to set the attribute correctly in the case of `auto_now` or `auto_now_add`.

If you do override this method, you must return the value of the attribute at the end. You should also update the model's attribute if you make any changes to the value so that code holding references to the model will always see the correct value.

### Specifying the form field for a model field

To customize the form field used by `ModelForm`, you can override `formfield()`.

The form field class can be specified via the `form_class` and `choices_form_class` arguments; the latter is used if the field has choices specified, the former otherwise. If these arguments are not provided, `CharField` or `TypedChoiceField` will be used.

All of the `kwargs` dictionary is passed directly to the form field's `__init__()` method. Normally, all you need to do is set up a good default for the `form_class` (and maybe `choices_form_class`) argument and then delegate further handling to the parent class. This might require you to write a custom form field (and even a form widget). See the [forms documentation](#) for information about this.

Continuing our ongoing example, we can write the `formfield()` method as:

```
class HandField(models.Field):
    # ...

    def formfield(self, **kwargs):
        # This is a fairly standard way to set up some defaults
        # while letting the caller override them.
        defaults = {'form_class': MyFormField}
        defaults.update(kwargs)
        return super(HandField, self).formfield(**defaults)
```

This assumes we've imported a `MyFormField` field class (which has its own default widget). This document doesn't cover the details of writing custom form fields.

### Emulating built-in field types

If you have created a `db_type()` method, you don't need to worry about `get_internal_type()` – it won't be used much. Sometimes, though, your database storage is similar in type to some other field, so you can use that other field's logic to create the right column.

For example:

```
class HandField(models.Field):
    # ...

    def get_internal_type(self):
        return 'CharField'
```

No matter which database backend we are using, this will mean that `migrate` and other SQL commands create the right column type for storing a string.

If `get_internal_type()` returns a string that is not known to Django for the database backend you are using – that is, it doesn't appear in `django.db.backends.<db_name>.base.DatabaseWrapper.data_types` – the string will still be used by the serializer, but the default `db_type()` method will return `None`. See the documentation of `db_type()` for reasons why this might be useful. Putting a descriptive string in as the type of the field for the serializer is a useful idea if you're ever going to be using the serializer output in some other place, outside of Django.

## Converting field data for serialization

To customize how the values are serialized by a serializer, you can override `value_to_string()`. Using `value_from_object()` is the best way to get the field's value prior to serialization. For example, since our `HandField` uses strings for its data storage anyway, we can reuse some existing conversion code:

```
class HandField(models.Field):
    # ...

    def value_to_string(self, obj):
        value = self.value_from_object(obj)
        return self.get_prep_value(value)
```

## Some general advice

Writing a custom field can be a tricky process, particularly if you're doing complex conversions between your Python types and your database and serialization formats. Here are a couple of tips to make things go more smoothly:

1. Look at the existing Django fields (in `django/db/models/fields/__init__.py`) for inspiration. Try to find a field that's similar to what you want and extend it a little bit, instead of creating an entirely new field from scratch.
2. Put a `__str__()` (`__unicode__()` on Python 2) method on the class you're wrapping up as a field. There are a lot of places where the default behavior of the field code is to call `force_text()` on the value. (In our examples in this document, `value` would be a `Hand` instance, not a `HandField`). So if your `__str__()` method (`__unicode__()` on Python 2) automatically converts to the string form of your Python object, you can save yourself a lot of work.

### 4.3.4 Writing a `FileField` subclass

In addition to the above methods, fields that deal with files have a few other special requirements which must be taken into account. The majority of the mechanics provided by `FileField`, such as controlling database storage and retrieval, can remain unchanged, leaving subclasses to deal with the challenge of supporting a particular type of file.

Django provides a `File` class, which is used as a proxy to the file's contents and operations. This can be subclassed to customize how the file is accessed, and what methods are available. It lives at `django.db.models.fields.files`, and its default behavior is explained in the [file documentation](#).

Once a subclass of `File` is created, the new `FileField` subclass must be told to use it. To do so, simply assign the new `File` subclass to the special `attr_class` attribute of the `FileField` subclass.

## A few suggestions

In addition to the above details, there are a few guidelines which can greatly improve the efficiency and readability of the field's code.

1. The source for Django's own `ImageField` (in `django/db/models/fields/files.py`) is a great example of how to subclass `FileField` to support a particular type of file, as it incorporates all of the techniques described above.
2. Cache file attributes wherever possible. Since files may be stored in remote storage systems, retrieving them may cost extra time, or even money, that isn't always necessary. Once a file is retrieved to obtain some data about its content, cache as much of that data as possible to reduce the number of times the file must be retrieved on subsequent calls for that information.

## 4.4 Custom Lookups

Django offers a wide variety of *built-in lookups* for filtering (for example, `exact` and `icontains`). This documentation explains how to write custom lookups and how to alter the working of existing lookups. For the API references of lookups, see the *Lookup API reference*.

### 4.4.1 A simple lookup example

Let's start with a simple custom lookup. We will write a custom lookup `ne` which works opposite to `exact`. `Author.objects.filter(name__ne='Jack')` will translate to the SQL:

```
"author"."name" <> 'Jack'
```

This SQL is backend independent, so we don't need to worry about different databases.

There are two steps to making this work. Firstly we need to implement the lookup, then we need to tell Django about it. The implementation is quite straightforward:

```
from django.db.models import Lookup

class NotEqual(Lookup):
    lookup_name = 'ne'

    def as_sql(self, compiler, connection):
        lhs, lhs_params = self.process_lhs(compiler, connection)
        rhs, rhs_params = self.process_rhs(compiler, connection)
        params = lhs_params + rhs_params
        return '%s <> %s' % (lhs, rhs), params
```

To register the `NotEqual` lookup we will just need to call `register_lookup` on the field class we want the lookup to be available. In this case, the lookup makes sense on all `Field` subclasses, so we register it with `Field` directly:

```
from django.db.models.fields import Field
Field.register_lookup(NotEqual)
```

Lookup registration can also be done using a decorator pattern:

```
from django.db.models.fields import Field

@Field.register_lookup
class NotEqualLookup(Lookup):
    # ...
```

We can now use `foo__ne` for any field `foo`. You will need to ensure that this registration happens before you try to create any queriesets using it. You could place the implementation in a `models.py` file, or register the lookup in the `ready()` method of an `AppConfig`.

Taking a closer look at the implementation, the first required attribute is `lookup_name`. This allows the ORM to understand how to interpret `name__ne` and use `NotEqual` to generate the SQL. By convention, these names are always lowercase strings containing only letters, but the only hard requirement is that it must not contain the string `__`.

We then need to define the `as_sql` method. This takes a `SQLCompiler` object, called `compiler`, and the active database connection. `SQLCompiler` objects are not documented, but the only thing we need to know about them is that they have a `compile()` method which returns a tuple containing an SQL string, and the parameters to be

interpolated into that string. In most cases, you don't need to use it directly and can pass it on to `process_lhs()` and `process_rhs()`.

A `Lookup` works against two values, `lhs` and `rhs`, standing for left-hand side and right-hand side. The left-hand side is usually a field reference, but it can be anything implementing the *query expression API*. The right-hand is the value given by the user. In the example `Author.objects.filter(name__ne='Jack')`, the left-hand side is a reference to the `name` field of the `Author` model, and `'Jack'` is the right-hand side.

We call `process_lhs` and `process_rhs` to convert them into the values we need for SQL using the `compiler` object described before. These methods return tuples containing some SQL and the parameters to be interpolated into that SQL, just as we need to return from our `as_sql` method. In the above example, `process_lhs` returns `('"author"."name"', [])` and `process_rhs` returns `('"%s"', ['Jack'])`. In this example there were no parameters for the left hand side, but this would depend on the object we have, so we still need to include them in the parameters we return.

Finally we combine the parts into an SQL expression with `<>`, and supply all the parameters for the query. We then return a tuple containing the generated SQL string and the parameters.

## 4.4.2 A simple transformer example

The custom lookup above is great, but in some cases you may want to be able to chain lookups together. For example, let's suppose we are building an application where we want to make use of the `abs()` operator. We have an `Experiment` model which records a start value, end value, and the change (start - end). We would like to find all experiments where the change was equal to a certain amount (`Experiment.objects.filter(change__abs=27)`), or where it did not exceed a certain amount (`Experiment.objects.filter(change__abs__lt=27)`).

---

**Note:** This example is somewhat contrived, but it nicely demonstrates the range of functionality which is possible in a database backend independent manner, and without duplicating functionality already in Django.

---

We will start by writing a `AbsoluteValue` transformer. This will use the SQL function `ABS()` to transform the value before comparison:

```
from django.db.models import Transform

class AbsoluteValue(Transform):
    lookup_name = 'abs'
    function = 'ABS'
```

Next, let's register it for `IntegerField`:

```
from django.db.models import IntegerField
IntegerField.register_lookup(AbsoluteValue)
```

We can now run the queries we had before. `Experiment.objects.filter(change__abs=27)` will generate the following SQL:

```
SELECT ... WHERE ABS("experiments"."change") = 27
```

By using `Transform` instead of `Lookup` it means we are able to chain further lookups afterwards. So `Experiment.objects.filter(change__abs__lt=27)` will generate the following SQL:

```
SELECT ... WHERE ABS("experiments"."change") < 27
```

Note that in case there is no other lookup specified, Django interprets `change__abs=27` as `change__abs__exact=27`.

When looking for which lookups are allowable after the `Transform` has been applied, Django uses the `output_field` attribute. We didn't need to specify this here as it didn't change, but supposing we were applying `AbsoluteValue` to some field which represents a more complex type (for example a point relative to an origin, or a complex number) then we may have wanted to specify that the transform returns a `FloatField` type for further lookups. This can be done by adding an `output_field` attribute to the transform:

```
from django.db.models import FloatField, Transform

class AbsoluteValue(Transform):
    lookup_name = 'abs'
    function = 'ABS'

    @property
    def output_field(self):
        return FloatField()
```

This ensures that further lookups like `abs__lte` behave as they would for a `FloatField`.

### 4.4.3 Writing an efficient `abs__lt` lookup

When using the above written `abs` lookup, the SQL produced will not use indexes efficiently in some cases. In particular, when we use `change__abs__lt=27`, this is equivalent to `change__gt=-27 AND change__lt=27`. (For the `lte` case we could use the SQL `BETWEEN`).

So we would like `Experiment.objects.filter(change__abs__lt=27)` to generate the following SQL:

```
SELECT .. WHERE "experiments"."change" < 27 AND "experiments"."change" > -27
```

The implementation is:

```
from django.db.models import Lookup

class AbsoluteValueLessThan(Lookup):
    lookup_name = 'lt'

    def as_sql(self, compiler, connection):
        lhs, lhs_params = compiler.compile(self.lhs.lhs)
        rhs, rhs_params = self.process_rhs(compiler, connection)
        params = lhs_params + rhs_params + lhs_params + rhs_params
        return '%s < %s AND %s > -%s' % (lhs, rhs, lhs, rhs), params

AbsoluteValue.register_lookup(AbsoluteValueLessThan)
```

There are a couple of notable things going on. First, `AbsoluteValueLessThan` isn't calling `process_lhs()`. Instead it skips the transformation of the `lhs` done by `AbsoluteValue` and uses the original `lhs`. That is, we want to get `"experiments"."change"` not `ABS("experiments"."change")`. Referring directly to `self.lhs.lhs` is safe as `AbsoluteValueLessThan` can be accessed only from the `AbsoluteValue` lookup, that is the `lhs` is always an instance of `AbsoluteValue`.

Notice also that as both sides are used multiple times in the query the `params` need to contain `lhs_params` and `rhs_params` multiple times.

The final query does the inversion (`27` to `-27`) directly in the database. The reason for doing this is that if the `self.rhs` is something else than a plain integer value (for example an `F()` reference) we can't do the transformations in Python.

**Note:** In fact, most lookups with `__abs` could be implemented as range queries like this, and on most database backends it is likely to be more sensible to do so as you can make use of the indexes. However with PostgreSQL you may want to add an index on `abs (change)` which would allow these queries to be very efficient.

---

#### 4.4.4 A bilateral transformer example

The `AbsoluteValue` example we discussed previously is a transformation which applies to the left-hand side of the lookup. There may be some cases where you want the transformation to be applied to both the left-hand side and the right-hand side. For instance, if you want to filter a queryset based on the equality of the left and right-hand side insensitively to some SQL function.

Let's examine the simple example of case-insensitive transformation here. This transformation isn't very useful in practice as Django already comes with a bunch of built-in case-insensitive lookups, but it will be a nice demonstration of bilateral transformations in a database-agnostic way.

We define an `UpperCase` transformer which uses the SQL function `UPPER()` to transform the values before comparison. We define `bilateral = True` to indicate that this transformation should apply to both `lhs` and `rhs`:

```
from django.db.models import Transform

class UpperCase(Transform):
    lookup_name = 'upper'
    function = 'UPPER'
    bilateral = True
```

Next, let's register it:

```
from django.db.models import CharField, TextField
CharField.register_lookup(UpperCase)
TextField.register_lookup(UpperCase)
```

Now, the queryset `Author.objects.filter(name__upper="doe")` will generate a case insensitive query like this:

```
SELECT ... WHERE UPPER("author"."name") = UPPER('doe')
```

#### 4.4.5 Writing alternative implementations for existing lookups

Sometimes different database vendors require different SQL for the same operation. For this example we will rewrite a custom implementation for MySQL for the `NotEqual` operator. Instead of `<>` we will be using `!=` operator. (Note that in reality almost all databases support both, including all the official databases supported by Django).

We can change the behavior on a specific backend by creating a subclass of `NotEqual` with a `as_mysql` method:

```
class MySQLNotEqual(NotEqual):
    def as_mysql(self, compiler, connection):
        lhs, lhs_params = self.process_lhs(compiler, connection)
        rhs, rhs_params = self.process_rhs(compiler, connection)
        params = lhs_params + rhs_params
        return '%s != %s' % (lhs, rhs), params

Field.register_lookup(MySQLNotEqual)
```

We can then register it with `Field`. It takes the place of the original `NotEqual` class as it has the same `lookup_name`.

When compiling a query, Django first looks for `as_%s % connection.vendor` methods, and then falls back to `as_sql`. The vendor names for the in-built backends are `sqlite`, `postgresql`, `oracle` and `mysql`.

#### 4.4.6 How Django determines the lookups and transforms which are used

In some cases you may wish to dynamically change which `Transform` or `Lookup` is returned based on the name passed in, rather than fixing it. As an example, you could have a field which stores coordinates or an arbitrary dimension, and wish to allow a syntax like `.filter(coords__x7=4)` to return the objects where the 7th coordinate has value 4. In order to do this, you would override `get_lookup` with something like:

```
class CoordinatesField(Field):
    def get_lookup(self, lookup_name):
        if lookup_name.startswith('x'):
            try:
                dimension = int(lookup_name[1:])
            except ValueError:
                pass
            else:
                return get_coordinate_lookup(dimension)
        return super(CoordinatesField, self).get_lookup(lookup_name)
```

You would then define `get_coordinate_lookup` appropriately to return a `Lookup` subclass which handles the relevant value of `dimension`.

There is a similarly named method called `get_transform()`. `get_lookup()` should always return a `Lookup` subclass, and `get_transform()` a `Transform` subclass. It is important to remember that `Transform` objects can be further filtered on, and `Lookup` objects cannot.

When filtering, if there is only one lookup name remaining to be resolved, we will look for a `Lookup`. If there are multiple names, it will look for a `Transform`. In the situation where there is only one name and a `Lookup` is not found, we look for a `Transform` and then the exact lookup on that `Transform`. All call sequences always end with a `Lookup`. To clarify:

- `.filter(myfield__mylookup)` will call `myfield.get_lookup('mylookup')`.
- `.filter(myfield__mytransform__mylookup)` will call `myfield.get_transform('mytransform')`, and then `mytransform.get_lookup('mylookup')`.
- `.filter(myfield__mytransform)` will first call `myfield.get_lookup('mytransform')`, which will fail, so it will fall back to calling `myfield.get_transform('mytransform')` and then `mytransform.get_lookup('exact')`.

## 4.5 Custom template tags and filters

Django's template language comes with a wide variety of *built-in tags and filters* designed to address the presentation logic needs of your application. Nevertheless, you may find yourself needing functionality that is not covered by the core set of template primitives. You can extend the template engine by defining custom tags and filters using Python, and then make them available to your templates using the `{% load %}` tag.

## 4.5.1 Code layout

The most common place to specify custom template tags and filters is inside a Django app. If they relate to an existing app, it makes sense to bundle them there; otherwise, they can be added to a new app. When a Django app is added to `INSTALLED_APPS`, any tags it defines in the conventional location described below are automatically made available to load within templates.

The app should contain a `templatetags` directory, at the same level as `models.py`, `views.py`, etc. If this doesn't already exist, create it - don't forget the `__init__.py` file to ensure the directory is treated as a Python package.

---

### Development server won't automatically restart

After adding the `templatetags` module, you will need to restart your server before you can use the tags or filters in templates.

Your custom tags and filters will live in a module inside the `templatetags` directory. The name of the module file is the name you'll use to load the tags later, so be careful to pick a name that won't clash with custom tags and filters in another app.

For example, if your custom tags/filters are in a file called `poll_extras.py`, your app layout might look like this:

```
polls/
  __init__.py
  models.py
  templatetags/
    __init__.py
    poll_extras.py
  views.py
```

And in your template you would use the following:

```
{% load poll_extras %}
```

The app that contains the custom tags must be in `INSTALLED_APPS` in order for the `{% load %}` tag to work. This is a security feature: It allows you to host Python code for many template libraries on a single host machine without enabling access to all of them for every Django installation.

There's no limit on how many modules you put in the `templatetags` package. Just keep in mind that a `{% load %}` statement will load tags/filters for the given Python module name, not the name of the app.

To be a valid tag library, the module must contain a module-level variable named `register` that is a `template.Library` instance, in which all the tags and filters are registered. So, near the top of your module, put the following:

```
from django import template

register = template.Library()
```

Alternatively, template tag modules can be registered through the `'libraries'` argument to `DjangoTemplates`. This is useful if you want to use a different label from the template tag module name when loading template tags. It also enables you to register tags without installing an application.

---

### Behind the scenes

For a ton of examples, read the source code for Django's default filters and tags. They're in `django/template/defaultfilters.py` and `django/template/defaulttags.py`, respectively.

For more information on the `load` tag, read its documentation.

## 4.5.2 Writing custom template filters

Custom filters are just Python functions that take one or two arguments:

- The value of the variable (input) – not necessarily a string.
- The value of the argument – this can have a default value, or be left out altogether.

For example, in the filter `{{ var|foo:"bar" }}`, the filter `foo` would be passed the variable `var` and the argument `"bar"`.

Since the template language doesn't provide exception handling, any exception raised from a template filter will be exposed as a server error. Thus, filter functions should avoid raising exceptions if there is a reasonable fallback value to return. In case of input that represents a clear bug in a template, raising an exception may still be better than silent failure which hides the bug.

Here's an example filter definition:

```
def cut(value, arg):
    """Removes all values of arg from the given string"""
    return value.replace(arg, '')
```

And here's an example of how that filter would be used:

```
{{ somevariable|cut:"0" }}
```

Most filters don't take arguments. In this case, just leave the argument out of your function. Example:

```
def lower(value): # Only one argument.
    """Converts a string into all lowercase"""
    return value.lower()
```

## Registering custom filters

```
django.template.Library.filter()
```

Once you've written your filter definition, you need to register it with your `Library` instance, to make it available to Django's template language:

```
register.filter('cut', cut)
register.filter('lower', lower)
```

The `Library.filter()` method takes two arguments:

1. The name of the filter – a string.
2. The compilation function – a Python function (not the name of the function as a string).

You can use `register.filter()` as a decorator instead:

```
@register.filter(name='cut')
def cut(value, arg):
    return value.replace(arg, '')

@register.filter
```

```
def lower(value):  
    return value.lower()
```

If you leave off the name argument, as in the second example above, Django will use the function's name as the filter name.

Finally, `register.filter()` also accepts three keyword arguments, `is_safe`, `needs_autoescape`, and `expects_localtime`. These arguments are described in [filters and auto-escaping](#) and [filters and time zones](#) below.

## Template filters that expect strings

```
django.template.defaultfilters.stringfilter()
```

If you're writing a template filter that only expects a string as the first argument, you should use the decorator `stringfilter`. This will convert an object to its string value before being passed to your function:

```
from django import template  
from django.template.defaultfilters import stringfilter  
  
register = template.Library()  
  
@register.filter  
@stringfilter  
def lower(value):  
    return value.lower()
```

This way, you'll be able to pass, say, an integer to this filter, and it won't cause an `AttributeError` (because integers don't have `lower()` methods).

## Filters and auto-escaping

When writing a custom filter, give some thought to how the filter will interact with Django's auto-escaping behavior. Note that three types of strings can be passed around inside the template code:

- **Raw strings** are the native Python `str` or `unicode` types. On output, they're escaped if auto-escaping is in effect and presented unchanged, otherwise.
- **Safe strings** are strings that have been marked safe from further escaping at output time. Any necessary escaping has already been done. They're commonly used for output that contains raw HTML that is intended to be interpreted as-is on the client side.

Internally, these strings are of type `SafeBytes` or `SafeText`. They share a common base class of `SafeData`, so you can test for them using code like:

```
if isinstance(value, SafeData):  
    # Do something with the "safe" string.  
    ...
```

Template filter code falls into one of two situations:

1. Your filter does not introduce any HTML-unsafe characters (`<`, `>`, `'`, `"` or `&`) into the result that were not already present. In this case, you can let Django take care of all the auto-escaping handling for you. All you need to do is set the `is_safe` flag to `True` when you register your filter function, like so:

```
@register.filter(is_safe=True)  
def myfilter(value):  
    return value
```

This flag tells Django that if a “safe” string is passed into your filter, the result will still be “safe” and if a non-safe string is passed in, Django will automatically escape it, if necessary.

You can think of this as meaning “this filter is safe – it doesn’t introduce any possibility of unsafe HTML.”

The reason `is_safe` is necessary is because there are plenty of normal string operations that will turn a `SafeData` object back into a normal `str` or `unicode` object and, rather than try to catch them all, which would be very difficult, Django repairs the damage after the filter has completed.

For example, suppose you have a filter that adds the string `xx` to the end of any input. Since this introduces no dangerous HTML characters to the result (aside from any that were already present), you should mark your filter with `is_safe`:

```
@register.filter(is_safe=True)
def add_xx(value):
    return '%sxx' % value
```

When this filter is used in a template where auto-escaping is enabled, Django will escape the output whenever the input is not already marked as “safe”.

By default, `is_safe` is `False`, and you can omit it from any filters where it isn’t required.

Be careful when deciding if your filter really does leave safe strings as safe. If you’re *removing* characters, you might inadvertently leave unbalanced HTML tags or entities in the result. For example, removing a `>` from the input might turn `<a>` into `<a`, which would need to be escaped on output to avoid causing problems. Similarly, removing a semicolon (`;`) can turn `&amp;` into `&amp;`, which is no longer a valid entity and thus needs further escaping. Most cases won’t be nearly this tricky, but keep an eye out for any problems like that when reviewing your code.

Marking a filter `is_safe` will coerce the filter’s return value to a string. If your filter should return a boolean or other non-string value, marking it `is_safe` will probably have unintended consequences (such as converting a boolean `False` to the string `'False'`).

- Alternatively, your filter code can manually take care of any necessary escaping. This is necessary when you’re introducing new HTML markup into the result. You want to mark the output as safe from further escaping so that your HTML markup isn’t escaped further, so you’ll need to handle the input yourself.

To mark the output as a safe string, use `django.utils.safestring.mark_safe()`.

Be careful, though. You need to do more than just mark the output as safe. You need to ensure it really *is* safe, and what you do depends on whether auto-escaping is in effect. The idea is to write filters that can operate in templates where auto-escaping is either on or off in order to make things easier for your template authors.

In order for your filter to know the current auto-escaping state, set the `needs_autoescape` flag to `True` when you register your filter function. (If you don’t specify this flag, it defaults to `False`). This flag tells Django that your filter function wants to be passed an extra keyword argument, called `autoescape`, that is `True` if auto-escaping is in effect and `False` otherwise. It is recommended to set the default of the `autoescape` parameter to `True`, so that if you call the function from Python code it will have escaping enabled by default.

For example, let’s write a filter that emphasizes the first character of a string:

```
from django import template
from django.utils.html import conditional_escape
from django.utils.safestring import mark_safe

register = template.Library()

@register.filter(needs_autoescape=True)
def initial_letter_filter(text, autoescape=True):
    first, other = text[0], text[1:]
    if autoescape:
```

```

    esc = conditional_escape
else:
    esc = lambda x: x
    result = '<strong>%s</strong>%s' % (esc(first), esc(other))
return mark_safe(result)

```

The `needs_autoescape` flag and the `autoescape` keyword argument mean that our function will know whether automatic escaping is in effect when the filter is called. We use `autoescape` to decide whether the input data needs to be passed through `django.utils.html.conditional_escape` or not. (In the latter case, we just use the identity function as the “escape” function.) The `conditional_escape()` function is like `escape()` except it only escapes input that is **not** a `SafeData` instance. If a `SafeData` instance is passed to `conditional_escape()`, the data is returned unchanged.

Finally, in the above example, we remember to mark the result as safe so that our HTML is inserted directly into the template without further escaping.

There’s no need to worry about the `is_safe` flag in this case (although including it wouldn’t hurt anything). Whenever you manually handle the auto-escaping issues and return a safe string, the `is_safe` flag won’t change anything either way.

**Warning:** Avoiding XSS vulnerabilities when reusing built-in filters

Django’s built-in filters have `autoescape=True` by default in order to get the proper autoescaping behavior and avoid a cross-site script vulnerability.

In older versions of Django, be careful when reusing Django’s built-in filters as `autoescape` defaults to `None`. You’ll need to pass `autoescape=True` to get autoescaping.

For example, if you wanted to write a custom filter called `urlize_and_linebreaks` that combined the `urlize` and `linebreaksbr` filters, the filter would look like:

```

from django.template.defaultfilters import linebreaksbr, urlize

@register.filter(needs_autoescape=True)
def urlize_and_linebreaks(text, autoescape=True):
    return linebreaksbr(
        urlize(text, autoescape=autoescape),
        autoescape=autoescape
    )

```

Then:

```

{{ comment|urlize_and_linebreaks }}

```

would be equivalent to:

```

{{ comment|urlize|linebreaksbr }}

```

## Filters and time zones

If you write a custom filter that operates on `datetime` objects, you’ll usually register it with the `expects_localtime` flag set to `True`:

```

@register.filter(expects_localtime=True)
def businesshours(value):
    try:
        return 9 <= value.hour < 17

```

```
except AttributeError:
    return ''
```

When this flag is set, if the first argument to your filter is a time zone aware datetime, Django will convert it to the current time zone before passing it to your filter when appropriate, according to *rules for time zones conversions in templates*.

### 4.5.3 Writing custom template tags

Tags are more complex than filters, because tags can do anything. Django provides a number of shortcuts that make writing most types of tags easier. First we'll explore those shortcuts, then explain how to write a tag from scratch for those cases when the shortcuts aren't powerful enough.

#### Simple tags

```
django.template.Library.simple_tag()
```

Many template tags take a number of arguments – strings or template variables – and return a result after doing some processing based solely on the input arguments and some external information. For example, a `current_time` tag might accept a format string and return the time as a string formatted accordingly.

To ease the creation of these types of tags, Django provides a helper function, `simple_tag`. This function, which is a method of `django.template.Library`, takes a function that accepts any number of arguments, wraps it in a render function and the other necessary bits mentioned above and registers it with the template system.

Our `current_time` function could thus be written like this:

```
import datetime
from django import template

register = template.Library()

@register.simple_tag
def current_time(format_string):
    return datetime.datetime.now().strftime(format_string)
```

A few things to note about the `simple_tag` helper function:

- Checking for the required number of arguments, etc., has already been done by the time our function is called, so we don't need to do that.
- The quotes around the argument (if any) have already been stripped away, so we just receive a plain string.
- If the argument was a template variable, our function is passed the current value of the variable, not the variable itself.

Unlike other tag utilities, `simple_tag` passes its output through `conditional_escape()` if the template context is in autoescape mode, to ensure correct HTML and protect you from XSS vulnerabilities.

If additional escaping is not desired, you will need to use `mark_safe()` if you are absolutely sure that your code does not contain XSS vulnerabilities. For building small HTML snippets, use of `format_html()` instead of `mark_safe()` is strongly recommended.

Auto-escaping for `simple_tag` as described in the previous two paragraphs was added.

If your template tag needs to access the current context, you can use the `takes_context` argument when registering your tag:

```
@register.simple_tag(takes_context=True)
def current_time(context, format_string):
    timezone = context['timezone']
    return your_get_current_time_method(timezone, format_string)
```

Note that the first argument *must* be called `context`.

For more information on how the `takes_context` option works, see the section on *inclusion tags*.

If you need to rename your tag, you can provide a custom name for it:

```
register.simple_tag(lambda x: x - 1, name='minusone')

@register.simple_tag(name='minustwo')
def some_function(value):
    return value - 2
```

`simple_tag` functions may accept any number of positional or keyword arguments. For example:

```
@register.simple_tag
def my_tag(a, b, *args, **kwargs):
    warning = kwargs['warning']
    profile = kwargs['profile']
    ...
    return ...
```

Then in the template any number of arguments, separated by spaces, may be passed to the template tag. Like in Python, the values for keyword arguments are set using the equal sign (“=”) and must be provided after the positional arguments. For example:

```
{% my_tag 123 "abcd" book.title warning=message|lower profile=user.profile %}
```

It’s possible to store the tag results in a template variable rather than directly outputting it. This is done by using the `as` argument followed by the variable name. Doing so enables you to output the content yourself where you see fit:

```
{% current_time "%Y-%m-%d %I:%M %p" as the_time %}
<p>The time is {{ the_time }}.</p>
```

## Inclusion tags

`django.template.Library.inclusion_tag()`

Another common type of template tag is the type that displays some data by rendering *another* template. For example, Django’s admin interface uses custom template tags to display the buttons along the bottom of the “add/change” form pages. Those buttons always look the same, but the link targets change depending on the object being edited – so they’re a perfect case for using a small template that is filled with details from the current object. (In the admin’s case, this is the `submit_row` tag.)

These sorts of tags are called “inclusion tags”.

Writing inclusion tags is probably best demonstrated by example. Let’s write a tag that outputs a list of choices for a given `Poll` object, such as was created in the *tutorials*. We’ll use the tag like this:

```
{% show_results poll %}
```

...and the output will be something like this:

```
<ul>
  <li>First choice</li>
  <li>Second choice</li>
  <li>Third choice</li>
</ul>
```

First, define the function that takes the argument and produces a dictionary of data for the result. The important point here is we only need to return a dictionary, not anything more complex. This will be used as a template context for the template fragment. Example:

```
def show_results(poll):
    choices = poll.choice_set.all()
    return {'choices': choices}
```

Next, create the template used to render the tag's output. This template is a fixed feature of the tag: the tag writer specifies it, not the template designer. Following our example, the template is very simple:

```
<ul>
{% for choice in choices %}
  <li> {{ choice }} </li>
{% endfor %}
</ul>
```

Now, create and register the inclusion tag by calling the `inclusion_tag()` method on a `Library` object. Following our example, if the above template is in a file called `results.html` in a directory that's searched by the template loader, we'd register the tag like this:

```
# Here, register is a django.template.Library instance, as before
@register.inclusion_tag('results.html')
def show_results(poll):
    ...
```

Alternatively it is possible to register the inclusion tag using a `django.template.Template` instance:

```
from django.template.loader import get_template
t = get_template('results.html')
register.inclusion_tag(t)(show_results)
```

...when first creating the function.

Sometimes, your inclusion tags might require a large number of arguments, making it a pain for template authors to pass in all the arguments and remember their order. To solve this, Django provides a `takes_context` option for inclusion tags. If you specify `takes_context` in creating a template tag, the tag will have no required arguments, and the underlying Python function will have one argument – the template context as of when the tag was called.

For example, say you're writing an inclusion tag that will always be used in a context that contains `home_link` and `home_title` variables that point back to the main page. Here's what the Python function would look like:

```
@register.inclusion_tag('link.html', takes_context=True)
def jump_link(context):
    return {
        'link': context['home_link'],
        'title': context['home_title'],
    }
```

Note that the first parameter to the function *must* be called `context`.

In that `register.inclusion_tag()` line, we specified `takes_context=True` and the name of the template. Here's what the template `link.html` might look like:

```
Jump directly to <a href="{{ link }}">{{ title }}</a>.
```

Then, any time you want to use that custom tag, load its library and call it without any arguments, like so:

```
{% jump_link %}
```

Note that when you're using `takes_context=True`, there's no need to pass arguments to the template tag. It automatically gets access to the context.

The `takes_context` parameter defaults to `False`. When it's set to `True`, the tag is passed the context object, as in this example. That's the only difference between this case and the previous `inclusion_tag` example.

`inclusion_tag` functions may accept any number of positional or keyword arguments. For example:

```
@register.inclusion_tag('my_template.html')
def my_tag(a, b, *args, **kwargs):
    warning = kwargs['warning']
    profile = kwargs['profile']
    ...
    return ...
```

Then in the template any number of arguments, separated by spaces, may be passed to the template tag. Like in Python, the values for keyword arguments are set using the equal sign (“=”) and must be provided after the positional arguments. For example:

```
{% my_tag 123 "abcd" book.title warning=message|lower profile=user.profile %}
```

## Assignment tags

`django.template.Library.assignment_tag()`

Deprecated since version 1.9: `simple_tag` can now store results in a template variable and should be used instead.

To ease the creation of tags setting a variable in the context, Django provides a helper function, `assignment_tag`. This function works the same way as `simple_tag()` except that it stores the tag's result in a specified context variable instead of directly outputting it.

Our earlier `current_time` function could thus be written like this:

```
@register.assignment_tag
def get_current_time(format_string):
    return datetime.datetime.now().strftime(format_string)
```

You may then store the result in a template variable using the `as` argument followed by the variable name, and output it yourself where you see fit:

```
{% get_current_time "%Y-%m-%d %I:%M %p" as the_time %}
<p>The time is {{ the_time }}.</p>
```

## Advanced custom template tags

Sometimes the basic features for custom template tag creation aren't enough. Don't worry, Django gives you complete access to the internals required to build a template tag from the ground up.

## A quick overview

The template system works in a two-step process: compiling and rendering. To define a custom template tag, you specify how the compilation works and how the rendering works.

When Django compiles a template, it splits the raw template text into ‘nodes’. Each node is an instance of `django.template.Node` and has a `render()` method. A compiled template is, simply, a list of `Node` objects. When you call `render()` on a compiled template object, the template calls `render()` on each `Node` in its node list, with the given context. The results are all concatenated together to form the output of the template.

Thus, to define a custom template tag, you specify how the raw template tag is converted into a `Node` (the compilation function), and what the node’s `render()` method does.

## Writing the compilation function

For each template tag the template parser encounters, it calls a Python function with the tag contents and the parser object itself. This function is responsible for returning a `Node` instance based on the contents of the tag.

For example, let’s write a full implementation of our simple template tag, `{% current_time %}`, that displays the current date/time, formatted according to a parameter given in the tag, in `strftime()` syntax. It’s a good idea to decide the tag syntax before anything else. In our case, let’s say the tag should be used like this:

```
<p>The time is {% current_time "%Y-%m-%d %I:%M %p" %}.</p>
```

The parser for this function should grab the parameter and create a `Node` object:

```
from django import template

def do_current_time(parser, token):
    try:
        # split_contents() knows not to split quoted strings.
        tag_name, format_string = token.split_contents()
    except ValueError:
        raise template.TemplateSyntaxError(
            "%r tag requires a single argument" % token.contents.split()[0]
        )
    if not (format_string[0] == format_string[-1] and format_string[0] in ('"', "'")):
        raise template.TemplateSyntaxError(
            "%r tag's argument should be in quotes" % tag_name
        )
    return CurrentTimeNode(format_string[1:-1])
```

Notes:

- `parser` is the template parser object. We don’t need it in this example.
- `token.contents` is a string of the raw contents of the tag. In our example, it’s `'current_time "%Y-%m-%d %I:%M %p"'`.
- The `token.split_contents()` method separates the arguments on spaces while keeping quoted strings together. The more straightforward `token.contents.split()` wouldn’t be as robust, as it would naively split on *all* spaces, including those within quoted strings. It’s a good idea to always use `token.split_contents()`.
- This function is responsible for raising `django.template.TemplateSyntaxError`, with helpful messages, for any syntax error.

- The `TemplateSyntaxError` exceptions use the `tag_name` variable. Don't hard-code the tag's name in your error messages, because that couples the tag's name to your function. `token.contents.split()[0]` will "always" be the name of your tag – even when the tag has no arguments.
- The function returns a `CurrentTimeNode` with everything the node needs to know about this tag. In this case, it just passes the argument – `"%Y-%m-%d %I:%M %p"`. The leading and trailing quotes from the template tag are removed in `format_string[1:-1]`.
- The parsing is very low-level. The Django developers have experimented with writing small frameworks on top of this parsing system, using techniques such as EBNF grammars, but those experiments made the template engine too slow. It's low-level because that's fastest.

## Writing the renderer

The second step in writing custom tags is to define a `Node` subclass that has a `render()` method.

Continuing the above example, we need to define `CurrentTimeNode`:

```
import datetime
from django import template

class CurrentTimeNode(template.Node):
    def __init__(self, format_string):
        self.format_string = format_string

    def render(self, context):
        return datetime.datetime.now().strftime(self.format_string)
```

Notes:

- `__init__()` gets the `format_string` from `do_current_time()`. Always pass any options/parameters/arguments to a `Node` via its `__init__()`.
- The `render()` method is where the work actually happens.
- `render()` should generally fail silently, particularly in a production environment. In some cases however, particularly if `context.template.engine.debug` is `True`, this method may raise an exception to make debugging easier. For example, several core tags raise `django.template.TemplateSyntaxError` if they receive the wrong number or type of arguments.

Ultimately, this decoupling of compilation and rendering results in an efficient template system, because a template can render multiple contexts without having to be parsed multiple times.

## Auto-escaping considerations

The output from template tags is **not** automatically run through the auto-escaping filters (with the exception of `simple_tag()` as described above). However, there are still a couple of things you should keep in mind when writing a template tag.

If the `render()` function of your template stores the result in a context variable (rather than returning the result in a string), it should take care to call `mark_safe()` if appropriate. When the variable is ultimately rendered, it will be affected by the auto-escape setting in effect at the time, so content that should be safe from further escaping needs to be marked as such.

Also, if your template tag creates a new context for performing some sub-rendering, set the auto-escape attribute to the current context's value. The `__init__` method for the `Context` class takes a parameter called `autoescape` that you can use for this purpose. For example:

```

from django.template import Context

def render(self, context):
    # ...
    new_context = Context({'var': obj}, autoescape=context.autoescape)
    # ... Do something with new_context ...

```

This is not a very common situation, but it's useful if you're rendering a template yourself. For example:

```

def render(self, context):
    t = context.template.engine.get_template('small_fragment.html')
    return t.render(Context({'var': obj}, autoescape=context.autoescape))

```

If we had neglected to pass in the current `context.autoescape` value to our new `Context` in this example, the results would have *always* been automatically escaped, which may not be the desired behavior if the template tag is used inside a `{% autoescape off %}` block.

### Thread-safety considerations

Once a node is parsed, its `render` method may be called any number of times. Since Django is sometimes run in multi-threaded environments, a single node may be simultaneously rendering with different contexts in response to two separate requests. Therefore, it's important to make sure your template tags are thread safe.

To make sure your template tags are thread safe, you should never store state information on the node itself. For example, Django provides a builtin `cycle` template tag that cycles among a list of given strings each time it's rendered:

```

{% for o in some_list %}
    <tr class="{% cycle 'row1' 'row2' %}">
        ...
    </tr>
{% endfor %}

```

A naive implementation of `CycleNode` might look something like this:

```

import itertools
from django import template

class CycleNode(template.Node):
    def __init__(self, cyclevars):
        self.cycle_iter = itertools.cycle(cyclevars)

    def render(self, context):
        return next(self.cycle_iter)

```

But, suppose we have two templates rendering the template snippet from above at the same time:

1. Thread 1 performs its first loop iteration, `CycleNode.render()` returns 'row1'
2. Thread 2 performs its first loop iteration, `CycleNode.render()` returns 'row2'
3. Thread 1 performs its second loop iteration, `CycleNode.render()` returns 'row1'
4. Thread 2 performs its second loop iteration, `CycleNode.render()` returns 'row2'

The `CycleNode` is iterating, but it's iterating globally. As far as Thread 1 and Thread 2 are concerned, it's always returning the same value. This is obviously not what we want!

To address this problem, Django provides a `render_context` that's associated with the `context` of the template that is currently being rendered. The `render_context` behaves like a Python dictionary, and should be used to store Node state between invocations of the `render` method.

Let's refactor our `CycleNode` implementation to use the `render_context`:

```
class CycleNode(template.Node):
    def __init__(self, cyclevars):
        self.cyclevars = cyclevars

    def render(self, context):
        if self not in context.render_context:
            context.render_context[self] = itertools.cycle(self.cyclevars)
        cycle_iter = context.render_context[self]
        return next(cycle_iter)
```

Note that it's perfectly safe to store global information that will not change throughout the life of the Node as an attribute. In the case of `CycleNode`, the `cyclevars` argument doesn't change after the Node is instantiated, so we don't need to put it in the `render_context`. But state information that is specific to the template that is currently being rendered, like the current iteration of the `CycleNode`, should be stored in the `render_context`.

---

**Note:** Notice how we used `self` to scope the `CycleNode` specific information within the `render_context`. There may be multiple `CycleNodes` in a given template, so we need to be careful not to clobber another node's state information. The easiest way to do this is to always use `self` as the key into `render_context`. If you're keeping track of several state variables, make `render_context[self]` a dictionary.

---

## Registering the tag

Finally, register the tag with your module's `Library` instance, as explained in [writing custom template filters](#) above. Example:

```
register.tag('current_time', do_current_time)
```

The `tag()` method takes two arguments:

1. The name of the template tag – a string. If this is left out, the name of the compilation function will be used.
2. The compilation function – a Python function (not the name of the function as a string).

As with filter registration, it is also possible to use this as a decorator:

```
@register.tag(name="current_time")
def do_current_time(parser, token):
    ...

@register.tag
def shout(parser, token):
    ...
```

If you leave off the `name` argument, as in the second example above, Django will use the function's name as the tag name.

## Passing template variables to the tag

Although you can pass any number of arguments to a template tag using `token.split_contents()`, the arguments are all unpacked as string literals. A little more work is required in order to pass dynamic content (a template variable) to a template tag as an argument.

While the previous examples have formatted the current time into a string and returned the string, suppose you wanted to pass in a `DateTimeField` from an object and have the template tag format that date-time:

```
<p>This post was last updated at {% format_time blog_entry.date_updated "%Y-%m-%d %I:
↪%M %p" %}.</p>
```

Initially, `token.split_contents()` will return three values:

1. The tag name `format_time`.
2. The string `'blog_entry.date_updated'` (without the surrounding quotes).
3. The formatting string `'"%Y-%m-%d %I:%M %p"'`. The return value from `split_contents()` will include the leading and trailing quotes for string literals like this.

Now your tag should begin to look like this:

```
from django import template

def do_format_time(parser, token):
    try:
        # split_contents() knows not to split quoted strings.
        tag_name, date_to_be_formatted, format_string = token.split_contents()
    except ValueError:
        raise template.TemplateSyntaxError(
            "%r tag requires exactly two arguments" % token.contents.split()[0]
        )
    if not (format_string[0] == format_string[-1] and format_string[0] in ('"', "'")):
        raise template.TemplateSyntaxError(
            "%r tag's argument should be in quotes" % tag_name
        )
    return FormatTimeNode(date_to_be_formatted, format_string[1:-1])
```

You also have to change the renderer to retrieve the actual contents of the `date_updated` property of the `blog_entry` object. This can be accomplished by using the `Variable()` class in `django.template`.

To use the `Variable` class, simply instantiate it with the name of the variable to be resolved, and then call `variable.resolve(context)`. So, for example:

```
class FormatTimeNode(template.Node):
    def __init__(self, date_to_be_formatted, format_string):
        self.date_to_be_formatted = template.Variable(date_to_be_formatted)
        self.format_string = format_string

    def render(self, context):
        try:
            actual_date = self.date_to_be_formatted.resolve(context)
            return actual_date.strftime(self.format_string)
        except template.VariableDoesNotExist:
            return ''
```

Variable resolution will throw a `VariableDoesNotExist` exception if it cannot resolve the string passed to it in the current context of the page.

## Setting a variable in the context

The above examples simply output a value. Generally, it's more flexible if your template tags set template variables instead of outputting values. That way, template authors can reuse the values that your template tags create.

To set a variable in the context, just use dictionary assignment on the context object in the `render()` method. Here's an updated version of `CurrentTimeNode` that sets a template variable `current_time` instead of outputting it:

```
import datetime
from django import template

class CurrentTimeNode2(template.Node):
    def __init__(self, format_string):
        self.format_string = format_string
    def render(self, context):
        context['current_time'] = datetime.datetime.now().strftime(self.format_string)
        return ''
```

Note that `render()` returns the empty string. `render()` should always return string output. If all the template tag does is set a variable, `render()` should return the empty string.

Here's how you'd use this new version of the tag:

```
{% current_time "%Y-%M-%d %I:%M %p" %}<p>The time is {{ current_time }}.</p>
```

---

## Variable scope in context

Any variable set in the context will only be available in the same block of the template in which it was assigned. This behavior is intentional; it provides a scope for variables so that they don't conflict with context in other blocks.

But, there's a problem with `CurrentTimeNode2`: The variable name `current_time` is hard-coded. This means you'll need to make sure your template doesn't use `{{ current_time }}` anywhere else, because the `{% current_time %}` will blindly overwrite that variable's value. A cleaner solution is to make the template tag specify the name of the output variable, like so:

```
{% current_time "%Y-%M-%d %I:%M %p" as my_current_time %}
<p>The current time is {{ my_current_time }}.</p>
```

To do that, you'll need to refactor both the compilation function and Node class, like so:

```
import re

class CurrentTimeNode3(template.Node):
    def __init__(self, format_string, var_name):
        self.format_string = format_string
        self.var_name = var_name
    def render(self, context):
        context[self.var_name] = datetime.datetime.now().strftime(self.format_string)
        return ''

def do_current_time(parser, token):
    # This version uses a regular expression to parse tag contents.
    try:
        # Splitting by None == splitting by spaces.
        tag_name, arg = token.contents.split(None, 1)
    except ValueError:
        raise template.TemplateSyntaxError(
```

```

        "%r tag requires arguments" % token.contents.split()[0]
    )
    m = re.search(r'(.*) as (\w+)', arg)
    if not m:
        raise template.TemplateSyntaxError("%r tag had invalid arguments" % tag_name)
    format_string, var_name = m.groups()
    if not (format_string[0] == format_string[-1] and format_string[0] in ('"', "'")):
        raise template.TemplateSyntaxError(
            "%r tag's argument should be in quotes" % tag_name
        )
    return CurrentTimeNode3(format_string[1:-1], var_name)

```

The difference here is that `do_current_time()` grabs the format string and the variable name, passing both to `CurrentTimeNode3`.

Finally, if you only need to have a simple syntax for your custom context-updating template tag, consider using the `simple_tag()` shortcut, which supports assigning the tag results to a template variable.

### Parsing until another block tag

Template tags can work in tandem. For instance, the standard `{% comment %}` tag hides everything until `{% endcomment %}`. To create a template tag such as this, use `parser.parse()` in your compilation function.

Here's how a simplified `{% comment %}` tag might be implemented:

```

def do_comment(parser, token):
    nodelist = parser.parse(('endcomment',))
    parser.delete_first_token()
    return CommentNode()

class CommentNode(template.Node):
    def render(self, context):
        return ''

```

**Note:** The actual implementation of `{% comment %}` is slightly different in that it allows broken template tags to appear between `{% comment %}` and `{% endcomment %}`. It does so by calling `parser.skip_past('endcomment')` instead of `parser.parse(('endcomment',))` followed by `parser.delete_first_token()`, thus avoiding the generation of a node list.

`parser.parse()` takes a tuple of names of block tags “to parse until”. It returns an instance of `django.template.NodeList`, which is a list of all `Node` objects that the parser encountered “before” it encountered any of the tags named in the tuple.

In `"nodelist = parser.parse(('endcomment',))"` in the above example, `nodelist` is a list of all nodes between the `{% comment %}` and `{% endcomment %}`, not counting `{% comment %}` and `{% endcomment %}` themselves.

After `parser.parse()` is called, the parser hasn't yet “consumed” the `{% endcomment %}` tag, so the code needs to explicitly call `parser.delete_first_token()`.

`CommentNode.render()` simply returns an empty string. Anything between `{% comment %}` and `{% endcomment %}` is ignored.

## Parsing until another block tag, and saving contents

In the previous example, `do_comment()` discarded everything between `{% comment %}` and `{% endcomment %}`. Instead of doing that, it's possible to do something with the code between block tags.

For example, here's a custom template tag, `{% upper %}`, that capitalizes everything between itself and `{% endupper %}`.

Usage:

```
{% upper %}This will appear in uppercase, {{ your_name }}.{% endupper %}
```

As in the previous example, we'll use `parser.parse()`. But this time, we pass the resulting `nodelist` to the `Node`:

```
def do_upper(parser, token):
    nodelist = parser.parse('endupper',)
    parser.delete_first_token()
    return UpperNode(nodelist)

class UpperNode(template.Node):
    def __init__(self, nodelist):
        self.nodelist = nodelist
    def render(self, context):
        output = self.nodelist.render(context)
        return output.upper()
```

The only new concept here is the `self.nodelist.render(context)` in `UpperNode.render()`.

For more examples of complex rendering, see the source code of `{% for %}` in `django/template/defaulttags.py` and `{% if %}` in `django/template/smartif.py`.

## 4.6 Writing a custom storage system

If you need to provide custom file storage – a common example is storing files on some remote system – you can do so by defining a custom storage class. You'll need to follow these steps:

1. Your custom storage system must be a subclass of `django.core.files.storage.Storage`:

```
from django.core.files.storage import Storage

class MyStorage(Storage):
    ...
```

2. Django must be able to instantiate your storage system without any arguments. This means that any settings should be taken from `django.conf.settings`:

```
from django.conf import settings
from django.core.files.storage import Storage

class MyStorage(Storage):
    def __init__(self, option=None):
        if not option:
            option = settings.CUSTOM_STORAGE_OPTIONS
        ...
```

3. Your storage class must implement the `_open()` and `_save()` methods, along with any other methods appropriate to your storage class. See below for more on these methods.

In addition, if your class provides local file storage, it must override the `path()` method.

4. Your storage class must be *deconstructible* so it can be serialized when it's used on a field in a migration. As long as your field has arguments that are themselves *serializable*, you can use the `django.utils.deconstruct.deconstructible` class decorator for this (that's what Django uses on `FileSystemStorage`).

By default, the following methods raise `NotImplementedError` and will typically have to be overridden:

- `Storage.delete()`
- `Storage.exists()`
- `Storage.listdir()`
- `Storage.size()`
- `Storage.url()`

Note however that not all these methods are required and may be deliberately omitted. As it happens, it is possible to leave each method unimplemented and still have a working `Storage`.

By way of example, if listing the contents of certain storage backends turns out to be expensive, you might decide not to implement `Storage.listdir`.

Another example would be a backend that only handles writing to files. In this case, you would not need to implement any of the above methods.

Ultimately, which of these methods are implemented is up to you. Leaving some methods unimplemented will result in a partial (possibly broken) interface.

You'll also usually want to use hooks specifically designed for custom storage objects. These are:

`_open(name, mode='rb')`

#### Required.

Called by `Storage.open()`, this is the actual mechanism the storage class uses to open the file. This must return a `File` object, though in most cases, you'll want to return some subclass here that implements logic specific to the backend storage system.

`_save(name, content)`

Called by `Storage.save()`. The `name` will already have gone through `get_valid_name()` and `get_available_name()`, and the `content` will be a `File` object itself.

Should return the actual name of the file saved (usually the `name` passed in, but if the storage needs to change the file name return the new name instead).

`get_valid_name(name)`

Returns a filename suitable for use with the underlying storage system. The `name` argument passed to this method is either the original filename sent to the server or, if `upload_to` is a callable, the filename returned by that method after any path information is removed. Override this to customize how non-standard characters are converted to safe filenames.

In older versions, this method was not called when `upload_to` was a callable.

The code provided on `Storage` retains only alpha-numeric characters, periods and underscores from the original filename, removing everything else.

`get_available_name(name, max_length=None)`

Returns a filename that is available in the storage mechanism, possibly taking the provided filename into account. The `name` argument passed to this method will have already cleaned to a filename valid for the storage system, according to the `get_valid_name()` method described above.

The length of the filename will not exceed `max_length`, if provided. If a free unique filename cannot be found, a `SuspiciousFileOperation` exception is raised.

If a file with `name` already exists, an underscore plus a random 7 character alphanumeric string is appended to the filename before the extension.

## 4.7 Deploying Django

Django’s chock-full of shortcuts to make Web developer’s lives easier, but all those tools are of no use if you can’t easily deploy your sites. Since Django’s inception, ease of deployment has been a major goal.

### 4.7.1 How to deploy with WSGI

Django’s primary deployment platform is [WSGI](#), the Python standard for web servers and applications.

Django’s `startproject` management command sets up a simple default WSGI configuration for you, which you can tweak as needed for your project, and direct any WSGI-compliant application server to use.

Django includes getting-started documentation for the following WSGI servers:

#### How to use Django with Apache and `mod_wsgi`

Deploying Django with [Apache](#) and `mod_wsgi` is a tried and tested way to get Django into production.

`mod_wsgi` is an Apache module which can host any Python [WSGI](#) application, including Django. Django will work with any version of Apache which supports `mod_wsgi`.

The [official `mod\_wsgi` documentation](#) is fantastic; it’s your source for all the details about how to use `mod_wsgi`. You’ll probably want to start with the [installation and configuration documentation](#).

#### Basic configuration

Once you’ve got `mod_wsgi` installed and activated, edit your Apache server’s `httpd.conf` file and add the following. If you are using a version of Apache older than 2.4, replace `Require all granted` with `Allow from all` and also add the line `Order deny,allow` above it.

```
WSGIScriptAlias / /path/to/mysite.com/mysite/wsgi.py
WSGIPythonHome /path/to/venv
WSGIPythonPath /path/to/mysite.com

<Directory /path/to/mysite.com/mysite>
<Files wsgi.py>
Require all granted
</Files>
</Directory>
```

The first bit in the `WSGIScriptAlias` line is the base URL path you want to serve your application at (`/` indicates the root url), and the second is the location of a “WSGI file” – see below – on your system, usually inside of your project package (`mysite` in this example). This tells Apache to serve any request below the given URL using the WSGI application defined in that file.

If you install your project’s Python dependencies inside a `virtualenv`, add the path to the `virtualenv` using `WSGI PythonHome`. See the [mod\\_wsgi virtualenv guide](#) for more details.

The `WSGI PythonPath` line ensures that your project package is available for import on the Python path; in other words, that `import mysite` works.

The `<Directory>` piece just ensures that Apache can access your `wsgi.py` file.

Next we’ll need to ensure this `wsgi.py` with a WSGI application object exists. As of Django version 1.4, `startproject` will have created one for you; otherwise, you’ll need to create it. See the [WSGI overview documentation](#) for the default contents you should put in this file, and what else you can add to it.

**Warning:** If multiple Django sites are run in a single `mod_wsgi` process, all of them will use the settings of whichever one happens to run first. This can be solved by changing:

```
os.environ.setdefault("DJANGO_SETTINGS_MODULE", "{ project_name }.settings")
```

in `wsgi.py`, to:

```
os.environ["DJANGO_SETTINGS_MODULE"] = "{ project_name }.settings"
```

or by [using mod\\_wsgi daemon mode](#) and ensuring that each site runs in its own daemon process.

---

### Fixing `UnicodeEncodeError` for file uploads

If you get a `UnicodeEncodeError` when uploading files with file names that contain non-ASCII characters, make sure Apache is configured to accept non-ASCII file names:

```
export LANG='en_US.UTF-8'  
export LC_ALL='en_US.UTF-8'
```

A common location to put this configuration is `/etc/apache2/envvars`.

See the [Files](#) section of the Unicode reference guide for details.

---

### Using `mod_wsgi` daemon mode

“Daemon mode” is the recommended mode for running `mod_wsgi` (on non-Windows platforms). To create the required daemon process group and delegate the Django instance to run in it, you will need to add appropriate `WSGIDaemonProcess` and `WSGIProcessGroup` directives. A further change required to the above configuration if you use daemon mode is that you can’t use `WSGI PythonPath`; instead you should use the `python-path` option to `WSGIDaemonProcess`, for example:

```
WSGIDaemonProcess example.com python-home=/path/to/venv python-path=/path/to/mysite.  
↪com  
WSGIProcessGroup example.com
```

If you want to serve your project in a subdirectory (`https://example.com/mysite` in this example), you can add `WSGIScriptAlias` to the configuration above:

```
WSGIScriptAlias /mysite /path/to/mysite.com/mysite/wsgi.py process-group=example.com
```

See the official `mod_wsgi` documentation for [details on setting up daemon mode](#).

## Serving files

Django doesn't serve files itself; it leaves that job to whichever Web server you choose.

We recommend using a separate Web server – i.e., one that's not also running Django – for serving media. Here are some good choices:

- [Nginx](#)
- A stripped-down version of [Apache](#)

If, however, you have no option but to serve media files on the same Apache `VirtualHost` as Django, you can set up Apache to serve some URLs as static media, and others using the `mod_wsgi` interface to Django.

This example sets up Django at the site root, but serves `robots.txt`, `favicon.ico`, and anything in the `/static/` and `/media/` URL space as a static file. All other URLs will be served using `mod_wsgi`:

```
Alias /robots.txt /path/to/mysite.com/static/robots.txt
Alias /favicon.ico /path/to/mysite.com/static/favicon.ico

Alias /media/ /path/to/mysite.com/media/
Alias /static/ /path/to/mysite.com/static/

<Directory /path/to/mysite.com/static>
Require all granted
</Directory>

<Directory /path/to/mysite.com/media>
Require all granted
</Directory>

WSGIScriptAlias / /path/to/mysite.com/mysite/wsgi.py

<Directory /path/to/mysite.com/mysite>
<Files wsgi.py>
Require all granted
</Files>
</Directory>
```

If you are using a version of Apache older than 2.4, replace `Require all granted` with `Allow from all` and also add the line `Order deny, allow` above it.

## Serving the admin files

When `django.contrib.staticfiles` is in `INSTALLED_APPS`, the Django development server automatically serves the static files of the admin app (and any other installed apps). This is however not the case when you use any other server arrangement. You're responsible for setting up Apache, or whichever Web server you're using, to serve the admin files.

The admin files live in (`django/contrib/admin/static/admin`) of the Django distribution.

We **strongly** recommend using `django.contrib.staticfiles` to handle the admin files (along with a Web server as outlined in the previous section; this means using the `collectstatic` management command to collect the static files in `STATIC_ROOT`, and then configuring your Web server to serve `STATIC_ROOT` at `STATIC_URL`), but here are three other approaches:

1. Create a symbolic link to the admin static files from within your document root (this may require `+FollowSymLinks` in your Apache configuration).

2. Use an `Alias` directive, as demonstrated above, to alias the appropriate URL (probably `STATIC_URL + admin/`) to the actual location of the admin files.
3. Copy the admin static files so that they live within your Apache document root.

## Authenticating against Django's user database from Apache

Django provides a handler to allow Apache to authenticate users directly against Django's authentication backends. See the [mod\\_wsgi authentication documentation](#).

## Authenticating against Django's user database from Apache

Since keeping multiple authentication databases in sync is a common problem when dealing with Apache, you can configure Apache to authenticate against Django's [authentication system](#) directly. This requires Apache version `>= 2.2` and `mod_wsgi >= 2.0`. For example, you could:

- Serve static/media files directly from Apache only to authenticated users.
- Authenticate access to a [Subversion](#) repository against Django users with a certain permission.
- Allow certain users to connect to a WebDAV share created with `mod_dav`.

---

**Note:** If you have installed a [custom user model](#) and want to use this default auth handler, it must support an `is_active` attribute. If you want to use group based authorization, your custom user must have a relation named 'groups', referring to a related object that has a 'name' field. You can also specify your own custom `mod_wsgi` auth handler if your custom cannot conform to these requirements.

---

## Authentication with mod\_wsgi

---

**Note:** The use of `WSGIApplicationGroup` `%{GLOBAL}` in the configurations below presumes that your Apache instance is running only one Django application. If you are running more than one Django application, please refer to the [Defining Application Groups](#) section of the `mod_wsgi` docs for more information about this setting.

---

Make sure that `mod_wsgi` is installed and activated and that you have followed the steps to setup [Apache with mod\\_wsgi](#).

Next, edit your Apache configuration to add a location that you want only authenticated users to be able to view:

```
WSGIScriptAlias / /path/to/mysite.com/mysite/wsgi.py
WSGIPythonPath /path/to/mysite.com

WSGIProcessGroup %{GLOBAL}
WSGIApplicationGroup %{GLOBAL}

<Location "/secret">
    AuthType Basic
    AuthName "Top Secret"
    Require valid-user
    AuthBasicProvider wsgi
    WSGIAuthUserScript /path/to/mysite.com/mysite/wsgi.py
</Location>
```

The `WSGIAuthUserScript` directive tells `mod_wsgi` to execute the `check_password` function in specified `wsgi` script, passing the user name and password that it receives from the prompt. In this example, the `WSGIAuthUserScript` is the same as the `WSGIScriptAlias` that defines your application *that is created by `django-admin startproject`*.

---

### Using Apache 2.2 with authentication

Make sure that `mod_auth_basic` and `mod_authz_user` are loaded.

These might be compiled statically into Apache, or you might need to use `LoadModule` to load them dynamically in your `httpd.conf`:

```
LoadModule auth_basic_module modules/mod_auth_basic.so
LoadModule authz_user_module modules/mod_authz_user.so
```

---

Finally, edit your WSGI script `mysite.wsgi` to tie Apache's authentication to your site's authentication mechanisms by importing the `check_password` function:

```
import os

os.environ['DJANGO_SETTINGS_MODULE'] = 'mysite.settings'

from django.contrib.auth.handlers.modwsgi import check_password

from django.core.handlers.wsgi import WSGIHandler
application = WSGIHandler()
```

Requests beginning with `/secret/` will now require a user to authenticate.

The [mod\\_wsgi access control mechanisms documentation](#) provides additional details and information about alternative methods of authentication.

### Authorization with `mod_wsgi` and Django groups

`mod_wsgi` also provides functionality to restrict a particular location to members of a group.

In this case, the Apache configuration should look like this:

```
WSGIScriptAlias / /path/to/mysite.com/mysite/wsgi.py

WSGIProcessGroup %{GLOBAL}
WSGIApplicationGroup %{GLOBAL}

<Location "/secret">
    AuthType Basic
    AuthName "Top Secret"
    AuthBasicProvider wsgi
    WSGIAuthUserScript /path/to/mysite.com/mysite/wsgi.py
    WSGIAuthGroupScript /path/to/mysite.com/mysite/wsgi.py
    Require group secret-agents
    Require valid-user
</Location>
```

To support the `WSGIAuthGroupScript` directive, the same WSGI script `mysite.wsgi` must also import the `groups_for_user` function which returns a list groups the given user belongs to.

```
from django.contrib.auth.handlers.modwsgi import check_password, groups_for_user
```

Requests for `/secret/` will now also require user to be a member of the “secret-agents” group.

## How to use Django with Gunicorn

**Gunicorn** (“Green Unicorn”) is a pure-Python WSGI server for UNIX. It has no dependencies and is easy to install and use.

### Installing Gunicorn

Installing gunicorn is as easy as `pip install gunicorn`. For more details, see the [gunicorn documentation](#).

### Running Django in Gunicorn as a generic WSGI application

When Gunicorn is installed, a `gunicorn` command is available which starts the Gunicorn server process. At its simplest, gunicorn just needs to be called with the location of a module containing a WSGI application object named *application*. So for a typical Django project, invoking gunicorn would look like:

```
gunicorn myproject.wsgi
```

This will start one process running one thread listening on `127.0.0.1:8000`. It requires that your project be on the Python path; the simplest way to ensure that is to run this command from the same directory as your `manage.py` file.

See Gunicorn’s [deployment documentation](#) for additional tips.

## How to use Django with uWSGI

**uWSGI** is a fast, self-healing and developer/sysadmin-friendly application container server coded in pure C.

### See also:

The uWSGI docs offer a [tutorial](#) covering Django, nginx, and uWSGI (one possible deployment setup of many). The docs below are focused on how to integrate Django with uWSGI.

### Prerequisite: uWSGI

The uWSGI wiki describes several [installation procedures](#). Using pip, the Python package manager, you can install any uWSGI version with a single command. For example:

```
# Install current stable version.
$ pip install uwsgi

# Or install LTS (long term support).
$ pip install https://projects.unbit.it/downloads/uwsgi-lts.tar.gz
```

**Warning:** Some distributions, including Debian and Ubuntu, ship an outdated version of uWSGI that does not conform to the WSGI specification. Versions prior to 1.2.6 do not call `close` on the response object after handling a request. In those cases the `request_finished` signal isn't sent. This can result in idle connections to database and memcache servers.

## uWSGI model

uWSGI operates on a client-server model. Your Web server (e.g., nginx, Apache) communicates with a `django-uwsgi` “worker” process to serve dynamic content. See uWSGI's [background documentation](#) for more detail.

## Configuring and starting the uWSGI server for Django

uWSGI supports multiple ways to configure the process. See uWSGI's [configuration documentation](#) and examples.

Here's an example command to start a uWSGI server:

```
uwsgi --chdir=/path/to/your/project \
      --module=mysite.wsgi:application \
      --env DJANGO_SETTINGS_MODULE=mysite.settings \
      --master --pidfile=/tmp/project-master.pid \
      --socket=127.0.0.1:49152 \           # can also be a file
      --processes=5 \                   # number of worker processes
      --uid=1000 --gid=2000 \           # if root, uwsgi can drop privileges
      --harakiri=20 \                   # respawn processes taking more than 20 seconds
      --max-requests=5000 \             # respawn processes after serving 5000 requests
      --vacuum \                         # clear environment on exit
      --home=/path/to/virtual/env \     # optional path to a virtualenv
      --daemonize=/var/log/uwsgi/yourproject.log # background the process
```

This assumes you have a top-level project package named `mysite`, and within it a module `mysite/wsgi.py` that contains a WSGI application object. This is the layout you'll have if you ran `django-admin startproject mysite` (using your own project name in place of `mysite`) with a recent version of Django. If this file doesn't exist, you'll need to create it. See the [How to deploy with WSGI](#) documentation for the default contents you should put in this file and what else you can add to it.

The Django-specific options here are:

- `chdir`: The path to the directory that needs to be on Python's import path – i.e., the directory containing the `mysite` package.
- `module`: The WSGI module to use – probably the `mysite.wsgi` module that `startproject` creates.
- `env`: Should probably contain at least `DJANGO_SETTINGS_MODULE`.
- `home`: Optional path to your project `virtualenv`.

Example ini configuration file:

```
[uwsgi]
chdir=/path/to/your/project
module=mysite.wsgi:application
master=True
pidfile=/tmp/project-master.pid
vacuum=True
max-requests=5000
daemonize=/var/log/uwsgi/yourproject.log
```

Example ini configuration file usage:

```
uwsgi --ini uwsgi.ini
```

---

### Fixing `UnicodeEncodeError` for file uploads

If you get a `UnicodeEncodeError` when uploading files with file names that contain non-ASCII characters, make sure uWSGI is configured to accept non-ASCII file names by adding this to your `uwsgi.ini`:

```
env = LANG=en_US.UTF-8
```

See the [Files](#) section of the Unicode reference guide for details.

---

See the uWSGI docs on [managing the uWSGI process](#) for information on starting, stopping and reloading the uWSGI workers.

### The application object

The key concept of deploying with WSGI is the `application` callable which the application server uses to communicate with your code. It's commonly provided as an object named `application` in a Python module accessible to the server.

The `startproject` command creates a file `<project_name>/wsgi.py` that contains such an `application` callable.

It's used both by Django's development server and in production WSGI deployments.

WSGI servers obtain the path to the `application` callable from their configuration. Django's built-in server, namely the `runserver` command, reads it from the `WSGI_APPLICATION` setting. By default, it's set to `<project_name>.wsgi.application`, which points to the `application` callable in `<project_name>/wsgi.py`.

### Configuring the settings module

When the WSGI server loads your application, Django needs to import the settings module — that's where your entire application is defined.

Django uses the `DJANGO_SETTINGS_MODULE` environment variable to locate the appropriate settings module. It must contain the dotted path to the settings module. You can use a different value for development and production; it all depends on how you organize your settings.

If this variable isn't set, the default `wsgi.py` sets it to `mysite.settings`, where `mysite` is the name of your project. That's how `runserver` discovers the default settings file by default.

---

**Note:** Since environment variables are process-wide, this doesn't work when you run multiple Django sites in the same process. This happens with `mod_wsgi`.

To avoid this problem, use `mod_wsgi`'s daemon mode with each site in its own daemon process, or override the value from the environment by enforcing `os.environ["DJANGO_SETTINGS_MODULE"] = "mysite.settings"` in your `wsgi.py`.

---

## Applying WSGI middleware

To apply [WSGI middleware](#) you can simply wrap the application object. For instance you could add these lines at the bottom of `wsgi.py`:

```
from helloworld.wsgi import HelloWorldApplication
application = HelloWorldApplication(application)
```

You could also replace the Django WSGI application with a custom WSGI application that later delegates to the Django WSGI application, if you want to combine a Django application with a WSGI application of another framework.

---

**Note:** Some third-party WSGI middleware do not call `close` on the response object after handling a request. In those cases the `request_finished` signal isn't sent. This can result in idle connections to database and memcache servers.

---

### 4.7.2 Deployment checklist

The Internet is a hostile environment. Before deploying your Django project, you should take some time to review your settings, with security, performance, and operations in mind.

Django includes many *security features*. Some are built-in and always enabled. Others are optional because they aren't always appropriate, or because they're inconvenient for development. For example, forcing HTTPS may not be suitable for all websites, and it's impractical for local development.

Performance optimizations are another category of trade-offs with convenience. For instance, caching is useful in production, less so for local development. Error reporting needs are also widely different.

The following checklist includes settings that:

- must be set properly for Django to provide the expected level of security;
- are expected to be different in each environment;
- enable optional security features;
- enable performance optimizations;
- provide error reporting.

Many of these settings are sensitive and should be treated as confidential. If you're releasing the source code for your project, a common practice is to publish suitable settings for development, and to use a private settings module for production.

#### Run `manage.py check --deploy`

Some of the checks described below can be automated using the `check --deploy` option. Be sure to run it against your production settings file as described in the option's documentation.

### Critical settings

#### `SECRET_KEY`

**The secret key must be a large random value and it must be kept secret.**

Make sure that the key used in production isn't used anywhere else and avoid committing it to source control. This reduces the number of vectors from which an attacker may acquire the key.

Instead of hardcoding the secret key in your settings module, consider loading it from an environment variable:

```
import os
SECRET_KEY = os.environ['SECRET_KEY']
```

or from a file:

```
with open('/etc/secret_key.txt') as f:
    SECRET_KEY = f.read().strip()
```

## DEBUG

### You must never enable debug in production.

You're certainly developing your project with `DEBUG = True`, since this enables handy features like full tracebacks in your browser.

For a production environment, though, this is a really bad idea, because it leaks lots of information about your project: excerpts of your source code, local variables, settings, libraries used, etc.

## Environment-specific settings

### ALLOWED\_HOSTS

When `DEBUG = False`, Django doesn't work at all without a suitable value for `ALLOWED_HOSTS`.

This setting is required to protect your site against some CSRF attacks. If you use a wildcard, you must perform your own validation of the `Host` HTTP header, or otherwise ensure that you aren't vulnerable to this category of attacks.

You should also configure the Web server that sits in front of Django to validate the host. It should respond with a static error page or ignore requests for incorrect hosts instead of forwarding the request to Django. This way you'll avoid spurious errors in your Django logs (or emails if you have error reporting configured that way). For example, on nginx you might setup a default server to return "444 No Response" on an unrecognized host:

```
server {
    listen 80 default_server;
    return 444;
}
```

## CACHES

If you're using a cache, connection parameters may be different in development and in production. Django defaults to per-process *local-memory caching* which may not be desirable.

Cache servers often have weak authentication. Make sure they only accept connections from your application servers.

If you're using Memcached, consider using *cached sessions* to improve performance.

## DATABASES

Database connection parameters are probably different in development and in production.

Database passwords are very sensitive. You should protect them exactly like `SECRET_KEY`.

For maximum security, make sure database servers only accept connections from your application servers.

If you haven't set up backups for your database, do it right now!

## EMAIL\_BACKEND and related settings

If your site sends emails, these values need to be set correctly.

By default, Django sends email from `webmaster@localhost` and `root@localhost`. However, some mail providers reject email from these addresses. To use different sender addresses, modify the `DEFAULT_FROM_EMAIL` and `SERVER_EMAIL` settings.

## STATIC\_ROOT and STATIC\_URL

Static files are automatically served by the development server. In production, you must define a `STATIC_ROOT` directory where `collectstatic` will copy them.

See *Managing static files (e.g. images, JavaScript, CSS)* for more information.

## MEDIA\_ROOT and MEDIA\_URL

Media files are uploaded by your users. They're untrusted! Make sure your web server never attempts to interpret them. For instance, if a user uploads a `.php` file, the web server shouldn't execute it.

Now is a good time to check your backup strategy for these files.

## HTTPS

Any website which allows users to log in should enforce site-wide HTTPS to avoid transmitting access tokens in clear. In Django, access tokens include the login/password, the session cookie, and password reset tokens. (You can't do much to protect password reset tokens if you're sending them by email.)

Protecting sensitive areas such as the user account or the admin isn't sufficient, because the same session cookie is used for HTTP and HTTPS. Your web server must redirect all HTTP traffic to HTTPS, and only transmit HTTPS requests to Django.

Once you've set up HTTPS, enable the following settings.

### CSRF\_COOKIE\_SECURE

Set this to `True` to avoid transmitting the CSRF cookie over HTTP accidentally.

### SESSION\_COOKIE\_SECURE

Set this to `True` to avoid transmitting the session cookie over HTTP accidentally.

## Performance optimizations

Setting `DEBUG = False` disables several features that are only useful in development. In addition, you can tune the following settings.

### CONN\_MAX\_AGE

Enabling *persistent database connections* can result in a nice speed-up when connecting to the database accounts for a significant part of the request processing time.

This helps a lot on virtualized hosts with limited network performance.

### TEMPLATES

Enabling the cached template loader often improves performance drastically, as it avoids compiling each template every time it needs to be rendered. See the *template loaders docs* for more information.

## Error reporting

By the time you push your code to production, it's hopefully robust, but you can't rule out unexpected errors. Thankfully, Django can capture errors and notify you accordingly.

### LOGGING

Review your logging configuration before putting your website in production, and check that it works as expected as soon as you have received some traffic.

See *Logging* for details on logging.

### ADMINS and MANAGERS

`ADMINS` will be notified of 500 errors by email.

`MANAGERS` will be notified of 404 errors. `IGNORABLE_404_URLS` can help filter out spurious reports.

See *Error reporting* for details on error reporting by email.

---

### Error reporting by email doesn't scale very well

Consider using an error monitoring system such as [Sentry](#) before your inbox is flooded by reports. Sentry can also aggregate logs.

---

## Customize the default error views

Django includes default views and templates for several HTTP error codes. You may want to override the default templates by creating the following templates in your root template directory: `404.html`, `500.html`, `403.html`, and `400.html`. The default views should suffice for 99% of Web applications, but if you desire to customize them, see these instructions which also contain details about the default templates:

- *The 404 (page not found) view*

- *The 500 (server error) view*
- *The 403 (HTTP Forbidden) view*
- *The 400 (bad request) view*

## Python Options

It's strongly recommended that you invoke the Python process running your Django application using the `-R` option or with the `PYTHONHASHSEED` environment variable set to `random`. This option is enabled by default starting with Python 3.3.

These options help protect your site from denial-of-service (DoS) attacks triggered by carefully crafted inputs. Such an attack can drastically increase CPU usage by causing worst-case performance when creating `dict` instances. See [oCERT advisory #2011-003](#) for more information.

If you're new to deploying Django and/or Python, we'd recommend you try *mod\_wsgi* first. In most cases it'll be the easiest, fastest, and most stable deployment choice.

## 4.8 Upgrading Django to a newer version

While it can be a complex process at times, upgrading to the latest Django version has several benefits:

- New features and improvements are added.
- Bugs are fixed.
- Older version of Django will eventually no longer receive security updates. (see *Supported versions*).
- Upgrading as each new Django release is available makes future upgrades less painful by keeping your code base up to date.

Here are some things to consider to help make your upgrade process as smooth as possible.

### 4.8.1 Required Reading

If it's your first time doing an upgrade, it is useful to read the *guide on the different release processes*.

Afterwards, you should familiarize yourself with the changes that were made in the new Django version(s):

- Read the *release notes* for each 'final' release from the one after your current Django version, up to and including the version to which you plan to upgrade.
- Look at the *deprecation timeline* for the relevant versions.

Pay particular attention to backwards incompatible changes to get a clear idea of what will be needed for a successful upgrade.

### 4.8.2 Dependencies

In most cases it will be necessary to upgrade to the latest version of your Django-related dependencies as well. If the Django version was recently released or if some of your dependencies are not well-maintained, some of your dependencies may not yet support the new Django version. In these cases you may have to wait until new versions of your dependencies are released.

### 4.8.3 Resolving deprecation warnings

Before upgrading, it's a good idea to resolve any deprecation warnings raised by your project while using your current version of Django. Fixing these warnings before upgrading ensures that you're informed about areas of the code that need altering.

In Python, deprecation warnings are silenced by default. You must turn them on using the `-Wall` Python command line option or the `PYTHONWARNINGS` environment variable. For example, to show warnings while running tests:

```
$ python -Wall manage.py test
```

If you're not using the Django test runner, you may need to also ensure that any console output is not captured which would hide deprecation warnings. For example, if you use `py.test`:

```
$ PYTHONWARNINGS=all py.test tests --capture=no
```

Resolve any deprecation warnings with your current version of Django before continuing the upgrade process.

Third party applications might use deprecated APIs in order to support multiple versions of Django, so deprecation warnings in packages you've installed don't necessarily indicate a problem. If a package doesn't support the latest version of Django, consider raising an issue or sending a pull request for it.

### 4.8.4 Installation

Once you're ready, it is time to *install the new Django version*. If you are using `virtualenv` and it is a major upgrade, you might want to set up a new environment with all the dependencies first.

Exactly which steps you will need to take depends on your installation process. The most convenient way is to use `pip` with the `--upgrade` or `-U` flag:

```
$ pip install -U Django
```

`pip` also automatically uninstalls the previous version of Django.

If you use some other installation process, you might have to manually *uninstall the old Django version* and should look at the complete installation instructions.

### 4.8.5 Testing

When the new environment is set up, *run the full test suite* for your application. Again, it's useful to turn on deprecation warnings on so they're shown in the test output (you can also use the flag if you test your app manually using `manage.py runserver`):

```
$ python -Wall manage.py test
```

After you have run the tests, fix any failures. While you have the release notes fresh in your mind, it may also be a good time to take advantage of new features in Django by refactoring your code to eliminate any deprecation warnings.

### 4.8.6 Deployment

When you are sufficiently confident your app works with the new version of Django, you're ready to go ahead and *deploy* your upgraded Django project.

If you are using caching provided by Django, you should consider clearing your cache after upgrading. Otherwise you may run into problems, for example, if you are caching pickled objects as these objects are not guaranteed to be

pickle-compatible across Django versions. A past instance of incompatibility was caching pickled `HttpResponse` objects, either directly or indirectly via the `cache_page()` decorator.

## 4.9 Error reporting

When you're running a public site you should always turn off the `DEBUG` setting. That will make your server run much faster, and will also prevent malicious users from seeing details of your application that can be revealed by the error pages.

However, running with `DEBUG` set to `False` means you'll never see errors generated by your site – everyone will just see your public error pages. You need to keep track of errors that occur in deployed sites, so Django can be configured to create reports with details about those errors.

### 4.9.1 Email reports

#### Server errors

When `DEBUG` is `False`, Django will email the users listed in the `ADMINS` setting whenever your code raises an unhandled exception and results in an internal server error (HTTP status code 500). This gives the administrators immediate notification of any errors. The `ADMINS` will get a description of the error, a complete Python traceback, and details about the HTTP request that caused the error.

---

**Note:** In order to send email, Django requires a few settings telling it how to connect to your mail server. At the very least, you'll need to specify `EMAIL_HOST` and possibly `EMAIL_HOST_USER` and `EMAIL_HOST_PASSWORD`, though other settings may be also required depending on your mail server's configuration. Consult *the Django settings documentation* for a full list of email-related settings.

---

By default, Django will send email from `root@localhost`. However, some mail providers reject all email from this address. To use a different sender address, modify the `SERVER_EMAIL` setting.

To activate this behavior, put the email addresses of the recipients in the `ADMINS` setting.

#### See also:

Server error emails are sent using the logging framework, so you can customize this behavior by *customizing your logging configuration*.

#### 404 errors

Django can also be configured to email errors about broken links (404 “page not found” errors). Django sends emails about 404 errors when:

- `DEBUG` is `False`;
- Your `MIDDLEWARE` setting includes `django.middleware.common.BrokenLinkEmailsMiddleware`.

If those conditions are met, Django will email the users listed in the `MANAGERS` setting whenever your code raises a 404 and the request has a referer. It doesn't bother to email for 404s that don't have a referer – those are usually just people typing in broken URLs or broken Web bots. It also ignores 404s when the referer is equal to the requested URL, since this behavior is from broken Web bots too.

In older versions, 404s were not ignored when the referer was equal to the requested URL.

**Note:** `BrokenLinkEmailsMiddleware` must appear before other middleware that intercepts 404 errors, such as `LocaleMiddleware` or `FlatpageFallbackMiddleware`. Put it towards the top of your `MIDDLEWARE` setting.

You can tell Django to stop reporting particular 404s by tweaking the `IGNORABLE_404_URLS` setting. It should be a list of compiled regular expression objects. For example:

```
import re
IGNORABLE_404_URLS = [
    re.compile(r'\.(php|cgi)$'),
    re.compile(r'^/phpmyadmin/'),
]
```

In this example, a 404 to any URL ending with `.php` or `.cgi` will *not* be reported. Neither will any URL starting with `/phpmyadmin/`.

The following example shows how to exclude some conventional URLs that browsers and crawlers often request:

```
import re
IGNORABLE_404_URLS = [
    re.compile(r'^/apple-touch-icon.*\.png$'),
    re.compile(r'^/favicon\.ico$'),
    re.compile(r'^/robots\.txt$'),
]
```

(Note that these are regular expressions, so we put a backslash in front of periods to escape them.)

If you'd like to customize the behavior of `django.middleware.common.BrokenLinkEmailsMiddleware` further (for example to ignore requests coming from web crawlers), you should subclass it and override its methods.

#### See also:

404 errors are logged using the logging framework. By default, these log records are ignored, but you can use them for error reporting by writing a handler and *configuring logging* appropriately.

## 4.9.2 Filtering error reports

**Warning:** Filtering sensitive data is a hard problem, and it's nearly impossible to guarantee that sensitive data won't leak into an error report. Therefore, error reports should only be available to trusted team members and you should avoid transmitting error reports unencrypted over the Internet (such as through email).

### Filtering sensitive information

Error reports are really helpful for debugging errors, so it is generally useful to record as much relevant information about those errors as possible. For example, by default Django records the *full traceback* for the exception raised, each *traceback frame's* local variables, and the `HttpRequest`'s *attributes*.

However, sometimes certain types of information may be too sensitive and thus may not be appropriate to be kept track of, for example a user's password or credit card number. So in addition to filtering out settings that appear to be sensitive as described in the *DEBUG* documentation, Django offers a set of function decorators to help you control which information should be filtered out of error reports in a production environment (that is, where `DEBUG` is set to `False`): `sensitive_variables()` and `sensitive_post_parameters()`.

**sensitive\_variables** (\*variables)

If a function (either a view or any regular callback) in your code uses local variables susceptible to contain sensitive information, you may prevent the values of those variables from being included in error reports using the `sensitive_variables` decorator:

```
from django.views.decorators.debug import sensitive_variables

@sensitive_variables('user', 'pw', 'cc')
def process_info(user):
    pw = user.pass_word
    cc = user.credit_card_number
    name = user.name
    ...
```

In the above example, the values for the `user`, `pw` and `cc` variables will be hidden and replaced with stars (`*****`) in the error reports, whereas the value of the `name` variable will be disclosed.

To systematically hide all local variables of a function from error logs, do not provide any argument to the `sensitive_variables` decorator:

```
@sensitive_variables()
def my_function():
    ...
```

---

**When using multiple decorators**

If the variable you want to hide is also a function argument (e.g. `user` in the following example), and if the decorated function has multiple decorators, then make sure to place `@sensitive_variables` at the top of the decorator chain. This way it will also hide the function argument as it gets passed through the other decorators:

```
@sensitive_variables('user', 'pw', 'cc')
@some_decorator
@another_decorator
def process_info(user):
    ...
```

**sensitive\_post\_parameters** (\*parameters)

If one of your views receives an `HttpRequest` object with `POST parameters` susceptible to contain sensitive information, you may prevent the values of those parameters from being included in the error reports using the `sensitive_post_parameters` decorator:

```
from django.views.decorators.debug import sensitive_post_parameters

@sensitive_post_parameters('pass_word', 'credit_card_number')
def record_user_profile(request):
    UserProfile.create(
        user=request.user,
        password=request.POST['pass_word'],
        credit_card=request.POST['credit_card_number'],
        name=request.POST['name'],
    )
    ...
```

In the above example, the values for the `pass_word` and `credit_card_number` POST parameters will be hidden and replaced with stars (`*****`) in the request's representation inside the error reports, whereas the

value of the `name` parameter will be disclosed.

To systematically hide all POST parameters of a request in error reports, do not provide any argument to the `sensitive_post_parameters` decorator:

```
@sensitive_post_parameters()
def my_view(request):
    ...
```

All POST parameters are systematically filtered out of error reports for certain `django.contrib.auth.views` views (`login`, `password_reset_confirm`, `password_change`, and `add_view` and `user_change_password` in the `auth` admin) to prevent the leaking of sensitive information such as user passwords.

## Custom error reports

All `sensitive_variables()` and `sensitive_post_parameters()` do is, respectively, annotate the decorated function with the names of sensitive variables and annotate the `HttpRequest` object with the names of sensitive POST parameters, so that this sensitive information can later be filtered out of reports when an error occurs. The actual filtering is done by Django's default error reporter filter: `django.views.debug.SafeExceptionReporterFilter`. This filter uses the decorators' annotations to replace the corresponding values with stars (`*****`) when the error reports are produced. If you wish to override or customize this default behavior for your entire site, you need to define your own filter class and tell Django to use it via the `DEFAULT_EXCEPTION_REPORTER_FILTER` setting:

```
DEFAULT_EXCEPTION_REPORTER_FILTER = 'path.to.your.CustomExceptionReporterFilter'
```

You may also control in a more granular way which filter to use within any given view by setting the `HttpRequest`'s `exception_reporter_filter` attribute:

```
def my_view(request):
    if request.user.is_authenticated:
        request.exception_reporter_filter = CustomExceptionReporterFilter()
    ...
```

Your custom filter class needs to inherit from `django.views.debug.SafeExceptionReporterFilter` and may override the following methods:

### class `SafeExceptionReporterFilter`

`SafeExceptionReporterFilter.is_active(request)`

Returns True to activate the filtering operated in the other methods. By default the filter is active if `DEBUG` is False.

`SafeExceptionReporterFilter.get_post_parameters(request)`

Returns the filtered dictionary of POST parameters. By default it replaces the values of sensitive parameters with stars (`*****`).

`SafeExceptionReporterFilter.get_traceback_frame_variables(request, tb_frame)`

Returns the filtered dictionary of local variables for the given traceback frame. By default it replaces the values of sensitive variables with stars (`*****`).

### See also:

You can also set up custom error reporting by writing a custom piece of *exception middleware*. If you do write custom error handling, it's a good idea to emulate Django's built-in error handling and only report/log errors if `DEBUG` is False.

## 4.10 Providing initial data for models

It's sometimes useful to pre-populate your database with hard-coded data when you're first setting up an app. You can provide initial data with fixtures or migrations.

### 4.10.1 Providing initial data with fixtures

A fixture is a collection of data that Django knows how to import into a database. The most straightforward way of creating a fixture if you've already got some data is to use the `manage.py dumpdata` command. Or, you can write fixtures by hand; fixtures can be written as JSON, XML or YAML (with `PyYAML` installed) documents. The [serialization documentation](#) has more details about each of these supported *serialization formats*.

As an example, though, here's what a fixture for a simple `Person` model might look like in JSON:

```
[
  {
    "model": "myapp.person",
    "pk": 1,
    "fields": {
      "first_name": "John",
      "last_name": "Lennon"
    }
  },
  {
    "model": "myapp.person",
    "pk": 2,
    "fields": {
      "first_name": "Paul",
      "last_name": "McCartney"
    }
  }
]
```

And here's that same fixture as YAML:

```
- model: myapp.person
  pk: 1
  fields:
    first_name: John
    last_name: Lennon
- model: myapp.person
  pk: 2
  fields:
    first_name: Paul
    last_name: McCartney
```

You'll store this data in a `fixtures` directory inside your app.

Loading data is easy: just call `manage.py loaddata <fixturename>`, where `<fixturename>` is the name of the fixture file you've created. Each time you run `loaddata`, the data will be read from the fixture and re-loaded into the database. Note this means that if you change one of the rows created by a fixture and then run `loaddata` again, you'll wipe out any changes you've made.

## Where Django finds fixture files

By default, Django looks in the `fixtures` directory inside each app for fixtures. You can set the `FIXTURE_DIRS` setting to a list of additional directories where Django should look.

When running `manage.py loaddata`, you can also specify a path to a fixture file, which overrides searching the usual directories.

### See also:

Fixtures are also used by the *testing framework* to help set up a consistent test environment.

## 4.10.2 Providing initial data with migrations

If you want to automatically load initial data for an app, don't use fixtures. Instead, create a migration for your application with `RunPython` or `RunSQL` operations.

## 4.11 Running Django on Jython

`Jython` is an implementation of Python that runs on the Java platform (JVM). This document will get you up and running with Django on top of Jython.

### 4.11.1 Installing Jython

Django works with Jython versions 2.7b2 and higher. See the `Jython` website for download and installation instructions.

### 4.11.2 Creating a servlet container

If you just want to experiment with Django, skip ahead to the next section; Django includes a lightweight Web server you can use for testing, so you won't need to set up anything else until you're ready to deploy Django in production.

If you want to use Django on a production site, use a Java servlet container, such as `Apache Tomcat`. Full JavaEE applications servers such as `GlassFish` or `JBoss` are also OK, if you need the extra features they include.

### 4.11.3 Installing Django

The next step is to install Django itself. This is exactly the same as installing Django on standard Python, so see *Remove any old versions of Django* and *Install the Django code* for instructions.

### 4.11.4 Installing Jython platform support libraries

The `django-jython` project contains database backends and management commands for Django/Jython development. Note that the builtin Django backends won't work on top of Jython.

To install it, follow the *installation instructions* detailed on the project website. Also, read the *database backends* documentation there.

### 4.11.5 Differences with Django on Jython

At this point, Django on Jython should behave nearly identically to Django running on standard Python. However, are a few differences to keep in mind:

- Remember to use the `jython` command instead of `python`. The documentation uses `python` for consistency, but if you're using Jython you'll want to mentally replace `python` with `jython` every time it occurs.
- Similarly, you'll need to use the `JYTHONPATH` environment variable instead of `PYTHONPATH`.
- Any part of Django that requires [Pillow](#) will not work.

## 4.12 Integrating Django with a legacy database

While Django is best suited for developing new applications, it's quite possible to integrate it into legacy databases. Django includes a couple of utilities to automate as much of this process as possible.

This document assumes you know the Django basics, as covered in the [tutorial](#).

Once you've got Django set up, you'll follow this general process to integrate with an existing database.

### 4.12.1 Give Django your database parameters

You'll need to tell Django what your database connection parameters are, and what the name of the database is. Do that by editing the `DATABASES` setting and assigning values to the following keys for the 'default' connection:

- `NAME`
- `ENGINE`
- `USER`
- `PASSWORD`
- `HOST`
- `PORT`

### 4.12.2 Auto-generate the models

Django comes with a utility called `inspectdb` that can create models by introspecting an existing database. You can view the output by running this command:

```
$ python manage.py inspectdb
```

Save this as a file by using standard Unix output redirection:

```
$ python manage.py inspectdb > models.py
```

This feature is meant as a shortcut, not as definitive model generation. See the [documentation of inspectdb](#) for more information.

Once you've cleaned up your models, name the file `models.py` and put it in the Python package that holds your app. Then add the app to your `INSTALLED_APPS` setting.

By default, `inspectdb` creates unmanaged models. That is, `managed = False` in the model's `Meta` class tells Django not to manage each table's creation, modification, and deletion:

```
class Person(models.Model):
    id = models.IntegerField(primary_key=True)
    first_name = models.CharField(max_length=70)
    class Meta:
        managed = False
        db_table = 'CENSUS_PERSONS'
```

If you do want to allow Django to manage the table's lifecycle, you'll need to change the *managed* option above to True (or simply remove it because True is its default value).

### 4.12.3 Install the core Django tables

Next, run the *migrate* command to install any extra needed database records such as admin permissions and content types:

```
$ python manage.py migrate
```

### 4.12.4 Test and tweak

Those are the basic steps – from here you'll want to tweak the models Django generated until they work the way you'd like. Try accessing your data via the Django database API, and try editing objects via Django's admin site, and edit the models file accordingly.

## 4.13 Outputting CSV with Django

This document explains how to output CSV (Comma Separated Values) dynamically using Django views. To do this, you can either use the Python CSV library or the Django template system.

### 4.13.1 Using the Python CSV library

Python comes with a CSV library, *csv*. The key to using it with Django is that the *csv* module's CSV-creation capability acts on file-like objects, and Django's *HttpResponse* objects are file-like objects.

Here's an example:

```
import csv
from django.http import HttpResponse

def some_view(request):
    # Create the HttpResponse object with the appropriate CSV header.
    response = HttpResponse(content_type='text/csv')
    response['Content-Disposition'] = 'attachment; filename="somefilename.csv"'

    writer = csv.writer(response)
    writer.writerow(['First row', 'Foo', 'Bar', 'Baz'])
    writer.writerow(['Second row', 'A', 'B', 'C', '"Testing"', "Here's a quote"])

    return response
```

The code and comments should be self-explanatory, but a few things deserve a mention:

- The response gets a special MIME type, `text/csv`. This tells browsers that the document is a CSV file, rather than an HTML file. If you leave this off, browsers will probably interpret the output as HTML, which will result in ugly, scary gobbledygook in the browser window.
- The response gets an additional `Content-Disposition` header, which contains the name of the CSV file. This filename is arbitrary; call it whatever you want. It'll be used by browsers in the "Save as..." dialog, etc.
- Hooking into the CSV-generation API is easy: Just pass `response` as the first argument to `csv.writer`. The `csv.writer` function expects a file-like object, and `HttpResponse` objects fit the bill.
- For each row in your CSV file, call `writer.writerow`, passing it an iterable object such as a list or tuple.
- The CSV module takes care of quoting for you, so you don't have to worry about escaping strings with quotes or commas in them. Just pass `writerow()` your raw strings, and it'll do the right thing.

---

## Handling Unicode on Python 2

Python 2's `csv` module does not support Unicode input. Since Django uses Unicode internally this means strings read from sources such as `HttpRequest` are potentially problematic. There are a few options for handling this:

- Manually encode all Unicode objects to a compatible encoding.
- Use the `UnicodeWriter` class provided in the [csv module's examples section](#).
- Use the [python-unicodcsv module](#), which aims to be a drop-in replacement for `csv` that gracefully handles Unicode.

For more information, see the Python documentation of the `csv` module.

---

## Streaming large CSV files

When dealing with views that generate very large responses, you might want to consider using Django's `StreamingHttpResponse` instead. For example, by streaming a file that takes a long time to generate you can avoid a load balancer dropping a connection that might have otherwise timed out while the server was generating the response.

In this example, we make full use of Python generators to efficiently handle the assembly and transmission of a large CSV file:

```
import csv

from django.utils.six.moves import range
from django.http import StreamingHttpResponse

class Echo(object):
    """An object that implements just the write method of the file-like
    interface.
    """
    def write(self, value):
        """Write the value by returning it, instead of storing in a buffer."""
        return value

def some_streaming_csv_view(request):
    """A view that streams a large CSV file."""
    # Generate a sequence of rows. The range is based on the maximum number of
    # rows that can be handled by a single sheet in most spreadsheet
    # applications.
    rows = ["Row {}".format(idx), str(idx)] for idx in range(65536)
```

```

pseudo_buffer = Echo()
writer = csv.writer(pseudo_buffer)
response = StreamingHttpResponse((writer.writerow(row) for row in rows),
                                content_type="text/csv")
response['Content-Disposition'] = 'attachment; filename="somefilename.csv"'
return response

```

### 4.13.2 Using the template system

Alternatively, you can use the *Django template system* to generate CSV. This is lower-level than using the convenient Python `csv` module, but the solution is presented here for completeness.

The idea here is to pass a list of items to your template, and have the template output the commas in a *for* loop.

Here's an example, which generates the same CSV file as above:

```

from django.http import HttpResponse
from django.template import loader, Context

def some_view(request):
    # Create the HttpResponse object with the appropriate CSV header.
    response = HttpResponse(content_type='text/csv')
    response['Content-Disposition'] = 'attachment; filename="somefilename.csv"'

    # The data is hard-coded here, but you could load it from a database or
    # some other source.
    csv_data = (
        ('First row', 'Foo', 'Bar', 'Baz'),
        ('Second row', 'A', 'B', 'C', '"Testing"', "Here's a quote"),
    )

    t = loader.get_template('my_template_name.txt')
    c = Context({
        'data': csv_data,
    })
    response.write(t.render(c))
    return response

```

The only difference between this example and the previous example is that this one uses template loading instead of the CSV module. The rest of the code – such as the `content_type='text/csv'` – is the same.

Then, create the template `my_template_name.txt`, with this template code:

```

{% for row in data %}"{{ row.0|addslashes }}"", "{{ row.1|addslashes }}"", "{{ row.
↵2|addslashes }}"", "{{ row.3|addslashes }}"", "{{ row.4|addslashes }}"
{% endfor %}

```

This template is quite basic. It just iterates over the given data and displays a line of CSV for each row. It uses the `addslashes` template filter to ensure there aren't any problems with quotes.

### 4.13.3 Other text-based formats

Notice that there isn't very much specific to CSV here – just the specific output format. You can use either of these techniques to output any text-based format you can dream of. You can also use a similar technique to generate arbitrary binary data; see *Outputting PDFs with Django* for an example.

## 4.14 Outputting PDFs with Django

This document explains how to output PDF files dynamically using Django views. This is made possible by the excellent, open-source [ReportLab](#) Python PDF library.

The advantage of generating PDF files dynamically is that you can create customized PDFs for different purposes – say, for different users or different pieces of content.

For example, Django was used at [kusports.com](#) to generate customized, printer-friendly NCAA tournament brackets, as PDF files, for people participating in a March Madness contest.

### 4.14.1 Install ReportLab

The ReportLab library is [available on PyPI](#). A [user guide](#) (not coincidentally, a PDF file) is also available for download. You can install ReportLab with `pip`:

```
$ pip install reportlab
```

Test your installation by importing it in the Python interactive interpreter:

```
>>> import reportlab
```

If that command doesn't raise any errors, the installation worked.

### 4.14.2 Write your view

The key to generating PDFs dynamically with Django is that the ReportLab API acts on file-like objects, and Django's `HttpResponse` objects are file-like objects.

Here's a “Hello World” example:

```
from reportlab.pdfgen import canvas
from django.http import HttpResponse

def some_view(request):
    # Create the HttpResponse object with the appropriate PDF headers.
    response = HttpResponse(content_type='application/pdf')
    response['Content-Disposition'] = 'attachment; filename="somefilename.pdf"'

    # Create the PDF object, using the response object as its "file."
    p = canvas.Canvas(response)

    # Draw things on the PDF. Here's where the PDF generation happens.
    # See the ReportLab documentation for the full list of functionality.
    p.drawString(100, 100, "Hello world.")

    # Close the PDF object cleanly, and we're done.
    p.showPage()
    p.save()
    return response
```

The code and comments should be self-explanatory, but a few things deserve a mention:

- The response gets a special MIME type, `application/pdf`. This tells browsers that the document is a PDF file, rather than an HTML file. If you leave this off, browsers will probably interpret the output as HTML, which would result in ugly, scary gobbledygook in the browser window.

- The response gets an additional `Content-Disposition` header, which contains the name of the PDF file. This filename is arbitrary: Call it whatever you want. It'll be used by browsers in the “Save as...” dialog, etc.
- The `Content-Disposition` header starts with `'attachment; '` in this example. This forces Web browsers to pop-up a dialog box prompting/confirming how to handle the document even if a default is set on the machine. If you leave off `'attachment; '`, browsers will handle the PDF using whatever program/plugin they've been configured to use for PDFs. Here's what that code would look like:

```
response['Content-Disposition'] = 'filename="somefilename.pdf"'
```

- Hooking into the ReportLab API is easy: Just pass `response` as the first argument to `canvas.Canvas`. The `Canvas` class expects a file-like object, and `HttpResponse` objects fit the bill.
- Note that all subsequent PDF-generation methods are called on the PDF object (in this case, `p`) – not on `response`.
- Finally, it's important to call `showPage()` and `save()` on the PDF file.

---

**Note:** ReportLab is not thread-safe. Some of our users have reported odd issues with building PDF-generating Django views that are accessed by many people at the same time.

---

### 4.14.3 Complex PDFs

If you're creating a complex PDF document with ReportLab, consider using the `io` library as a temporary holding place for your PDF file. This library provides a file-like object interface that is particularly efficient. Here's the above “Hello World” example rewritten to use `io`:

```
from io import BytesIO
from reportlab.pdfgen import canvas
from django.http import HttpResponse

def some_view(request):
    # Create the HttpResponse object with the appropriate PDF headers.
    response = HttpResponse(content_type='application/pdf')
    response['Content-Disposition'] = 'attachment; filename="somefilename.pdf"'

    buffer = BytesIO()

    # Create the PDF object, using the BytesIO object as its "file."
    p = canvas.Canvas(buffer)

    # Draw things on the PDF. Here's where the PDF generation happens.
    # See the ReportLab documentation for the full list of functionality.
    p.drawString(100, 100, "Hello world.")

    # Close the PDF object cleanly.
    p.showPage()
    p.save()

    # Get the value of the BytesIO buffer and write it to the response.
    pdf = buffer.getvalue()
    buffer.close()
    response.write(pdf)
    return response
```

#### 4.14.4 Other formats

Notice that there isn't a lot in these examples that's PDF-specific – just the bits using `reportlab`. You can use a similar technique to generate any arbitrary format that you can find a Python library for. Also see *Outputting CSV with Django* for another example and some techniques you can use when generated text-based formats.

**See also:**

Django Packages provides a [comparison of packages](#) that help generate PDF files from Django.

### 4.15 Managing static files (e.g. images, JavaScript, CSS)

Websites generally need to serve additional files such as images, JavaScript, or CSS. In Django, we refer to these files as “static files”. Django provides `django.contrib.staticfiles` to help you manage them.

This page describes how you can serve these static files.

#### 4.15.1 Configuring static files

1. Make sure that `django.contrib.staticfiles` is included in your `INSTALLED_APPS`.
2. In your settings file, define `STATIC_URL`, for example:

```
STATIC_URL = '/static/'
```

3. In your templates, either hardcode the url like `/static/my_app/example.jpg` or, preferably, use the `static` template tag to build the URL for the given relative path by using the configured `STATICFILES_STORAGE` storage (this makes it much easier when you want to switch to a content delivery network (CDN) for serving static files).

```
{% load static %}

```

4. Store your static files in a folder called `static` in your app. For example `my_app/static/my_app/example.jpg`.

---

#### Serving the files

In addition to these configuration steps, you'll also need to actually serve the static files.

During development, if you use `django.contrib.staticfiles`, this will be done automatically by `runserver` when `DEBUG` is set to `True` (see `django.contrib.staticfiles.views.serve()`).

This method is **grossly inefficient** and probably **insecure**, so it is **unsuitable for production**.

See *Deploying static files* for proper strategies to serve static files in production environments.

---

Your project will probably also have static assets that aren't tied to a particular app. In addition to using a `static/` directory inside your apps, you can define a list of directories (`STATICFILES_DIRS`) in your settings file where Django will also look for static files. For example:

```
STATICFILES_DIRS = [
    os.path.join(BASE_DIR, "static"),
    '/var/www/static/',
]
```

See the documentation for the `STATICFILES_FINDERS` setting for details on how `staticfiles` finds your files.

---

### Static file namespacing

Now we *might* be able to get away with putting our static files directly in `my_app/static/` (rather than creating another `my_app` subdirectory), but it would actually be a bad idea. Django will use the first static file it finds whose name matches, and if you had a static file with the same name in a *different* application, Django would be unable to distinguish between them. We need to be able to point Django at the right one, and the easiest way to ensure this is by *namespacing* them. That is, by putting those static files inside *another* directory named for the application itself.

---

## 4.15.2 Serving static files during development

If you use `django.contrib.staticfiles` as explained above, `runserver` will do this automatically when `DEBUG` is set to `True`. If you don't have `django.contrib.staticfiles` in `INSTALLED_APPS`, you can still manually serve static files using the `django.contrib.staticfiles.views.serve()` view.

This is not suitable for production use! For some common deployment strategies, see [Deploying static files](#).

For example, if your `STATIC_URL` is defined as `/static/`, you can do this by adding the following snippet to your `urls.py`:

```
from django.conf import settings
from django.conf.urls.static import static

urlpatterns = [
    # ... the rest of your URLconf goes here ...
] + static(settings.STATIC_URL, document_root=settings.STATIC_ROOT)
```

---

**Note:** This helper function works only in debug mode and only if the given prefix is local (e.g. `/static/`) and not a URL (e.g. `http://static.example.com/`).

Also this helper function only serves the actual `STATIC_ROOT` folder; it doesn't perform static files discovery like `django.contrib.staticfiles`.

---

## 4.15.3 Serving files uploaded by a user during development

During development, you can serve user-uploaded media files from `MEDIA_ROOT` using the `django.contrib.staticfiles.views.serve()` view.

This is not suitable for production use! For some common deployment strategies, see [Deploying static files](#).

For example, if your `MEDIA_URL` is defined as `/media/`, you can do this by adding the following snippet to your `urls.py`:

```
from django.conf import settings
from django.conf.urls.static import static

urlpatterns = [
    # ... the rest of your URLconf goes here ...
] + static(settings.MEDIA_URL, document_root=settings.MEDIA_ROOT)
```

**Note:** This helper function works only in debug mode and only if the given prefix is local (e.g. `/media/`) and not a URL (e.g. `http://media.example.com/`).

---

#### 4.15.4 Testing

When running tests that use actual HTTP requests instead of the built-in testing client (i.e. when using the built-in `LiveServerTestCase`) the static assets need to be served along the rest of the content so the test environment reproduces the real one as faithfully as possible, but `LiveServerTestCase` has only very basic static file-serving functionality: It doesn't know about the finders feature of the `staticfiles` application and assumes the static content has already been collected under `STATIC_ROOT`.

Because of this, `staticfiles` ships its own `django.contrib.staticfiles.testing.StaticLiveServerTestCase`, a subclass of the built-in one that has the ability to transparently serve all the assets during execution of these tests in a way very similar to what we get at development time with `DEBUG = True`, i.e. without having to collect them using `collectstatic` first.

#### 4.15.5 Deployment

`django.contrib.staticfiles` provides a convenience management command for gathering static files in a single directory so you can serve them easily.

1. Set the `STATIC_ROOT` setting to the directory from which you'd like to serve these files, for example:

```
STATIC_ROOT = "/var/www/example.com/static/"
```

2. Run the `collectstatic` management command:

```
$ python manage.py collectstatic
```

This will copy all files from your static folders into the `STATIC_ROOT` directory.

3. Use a web server of your choice to serve the files. *Deploying static files* covers some common deployment strategies for static files.

#### 4.15.6 Learn more

This document has covered the basics and some common usage patterns. For complete details on all the settings, commands, template tags, and other pieces included in `django.contrib.staticfiles`, see *the staticfiles reference*.

### 4.16 Deploying static files

#### See also:

For an introduction to the use of `django.contrib.staticfiles`, see *Managing static files (e.g. images, JavaScript, CSS)*.

### 4.16.1 Serving static files in production

The basic outline of putting static files into production is simple: run the `collectstatic` command when static files change, then arrange for the collected static files directory (`STATIC_ROOT`) to be moved to the static file server and served. Depending on `STATICFILES_STORAGE`, files may need to be moved to a new location manually or the `post_process` method of the `Storage` class might take care of that.

Of course, as with all deployment tasks, the devil's in the details. Every production setup will be a bit different, so you'll need to adapt the basic outline to fit your needs. Below are a few common patterns that might help.

#### Serving the site and your static files from the same server

If you want to serve your static files from the same server that's already serving your site, the process may look something like:

- Push your code up to the deployment server.
- On the server, run `collectstatic` to copy all the static files into `STATIC_ROOT`.
- Configure your web server to serve the files in `STATIC_ROOT` under the URL `STATIC_URL`. For example, here's [how to do this with Apache and mod\\_wsgi](#).

You'll probably want to automate this process, especially if you've got multiple web servers. There's any number of ways to do this automation, but one option that many Django developers enjoy is [Fabric](#).

Below, and in the following sections, we'll show off a few example fabfiles (i.e. Fabric scripts) that automate these file deployment options. The syntax of a fabfile is fairly straightforward but won't be covered here; consult [Fabric's documentation](#), for a complete explanation of the syntax.

So, a fabfile to deploy static files to a couple of web servers might look something like:

```
from fabric.api import *

# Hosts to deploy onto
env.hosts = ['www1.example.com', 'www2.example.com']

# Where your project code lives on the server
env.project_root = '/home/www/myproject'

def deploy_static():
    with cd(env.project_root):
        run('./manage.py collectstatic -v0 --noinput')
```

#### Serving static files from a dedicated server

Most larger Django sites use a separate Web server – i.e., one that's not also running Django – for serving static files. This server often runs a different type of web server – faster but less full-featured. Some common choices are:

- [Nginx](#)
- A stripped-down version of [Apache](#)

Configuring these servers is out of scope of this document; check each server's respective documentation for instructions.

Since your static file server won't be running Django, you'll need to modify the deployment strategy to look something like:

- When your static files change, run `collectstatic` locally.

- Push your local `STATIC_ROOT` up to the static file server into the directory that's being served. `rsync` is a common choice for this step since it only needs to transfer the bits of static files that have changed.

Here's how this might look in a fabfile:

```
from fabric.api import *
from fabric.contrib import project

# Where the static files get collected locally. Your STATIC_ROOT setting.
env.local_static_root = '/path/to/static'

# Where the static files should go remotely
env.remote_static_root = '/home/www/static.example.com'

@roles('static')
def deploy_static():
    local('./manage.py collectstatic')
    project.rsync_project(
        remote_dir=env.remote_static_root,
        local_dir=env.local_static_root,
        delete=True,
    )
```

## Serving static files from a cloud service or CDN

Another common tactic is to serve static files from a cloud storage provider like Amazon's S3 and/or a CDN (content delivery network). This lets you ignore the problems of serving static files and can often make for faster-loading Web pages (especially when using a CDN).

When using these services, the basic workflow would look a bit like the above, except that instead of using `rsync` to transfer your static files to the server you'd need to transfer the static files to the storage provider or CDN.

There's any number of ways you might do this, but if the provider has an API a *custom file storage backend* will make the process incredibly simple. If you've written or are using a 3rd party custom storage backend, you can tell `collectstatic` to use it by setting `STATICFILES_STORAGE` to the storage engine.

For example, if you've written an S3 storage backend in `myproject.storage.S3Storage` you could use it with:

```
STATICFILES_STORAGE = 'myproject.storage.S3Storage'
```

Once that's done, all you have to do is run `collectstatic` and your static files would be pushed through your storage package up to S3. If you later needed to switch to a different storage provider, it could be as simple as changing your `STATICFILES_STORAGE` setting.

For details on how you'd write one of these backends, see *Writing a custom storage system*. There are 3rd party apps available that provide storage backends for many common file storage APIs. A good starting point is the [overview at djangopackages.com](http://overview.djangopackages.com).

### 4.16.2 Learn more

For complete details on all the settings, commands, template tags, and other pieces included in `django.contrib.staticfiles`, see *the staticfiles reference*.

## 4.17 How to install Django on Windows

This document will guide you through installing Python 3.5 and Django on Windows. It also provides instructions for installing `virtualenv` and `virtualenvwrapper`, which make it easier to work on Python projects. This is meant as a beginner’s guide for users working on Django projects and does not reflect how Django should be installed when developing patches for Django itself.

The steps in this guide have been tested with Windows 7, 8, and 10. In other versions, the steps would be similar. You will need to be familiar with using the Windows command prompt.

### 4.17.1 Install Python

Django is a Python web framework, thus requiring Python to be installed on your machine. At the time of writing, Python 3.5 is the latest version.

To install Python on your machine go to <https://python.org/downloads/>. The website should offer you a download button for the latest Python version. Download the executable installer and run it. Check the box next to Add Python 3.5 to PATH and then click Install Now.

After installation, open the command prompt and check that the Python version matches the version you installed by executing:

```
python --version
```

### 4.17.2 About pip

`pip` is a package manager for Python. It makes installing and uninstalling Python packages (such as Django!) very easy. For the rest of the installation, we’ll use `pip` to install Python packages from the command line.

To install `pip` on your machine, go to <https://pip.pypa.io/en/latest/installing/>, and follow the Installing with `get-pip.py` instructions.

### 4.17.3 Install virtualenv and virtualenvwrapper

`virtualenv` and `virtualenvwrapper` provide a dedicated environment for each Django project you create. While not mandatory, this is considered a best practice and will save you time in the future when you’re ready to deploy your project. Simply type:

```
pip install virtualenvwrapper-win
```

Then create a virtual environment for your project:

```
mkvirtualenv myproject
```

The virtual environment will be activated automatically and you’ll see “(myproject)” next to the command prompt to designate that. If you start a new command prompt, you’ll need to activate the environment again using:

```
workon myproject
```

## 4.17.4 Install Django

Django can be installed easily using `pip` within your virtual environment.

In the command prompt, ensure your virtual environment is active, and execute the following command:

```
pip install django
```

This will download and install the latest Django release.

After the installation has completed, you can verify your Django installation by executing `django-admin --version` in the command prompt.

See *Get your database running* for information on database installation with Django.

## 4.17.5 Common pitfalls

- If `django-admin` only displays the help text no matter what arguments it is given, there is probably a problem with the file association in Windows. Check if there is more than one environment variable set for running Python scripts in `PATH`. This usually occurs when there is more than one Python version installed.
- If you are connecting to the internet behind a proxy, there might be problem in running the command `pip install django`. Set the environment variables for proxy configuration in the command prompt as follows:

```
set http_proxy=http://username:password@proxyserver:proxyport
set https_proxy=https://username:password@proxyserver:proxyport
```

## 4.18 Writing database migrations

This document explains how to structure and write database migrations for different scenarios you might encounter. For introductory material on migrations, see *the topic guide*.

### 4.18.1 Data migrations and multiple databases

When using multiple databases, you may need to figure out whether or not to run a migration against a particular database. For example, you may want to **only** run a migration on a particular database.

In order to do that you can check the database connection's alias inside a `RunPython` operation by looking at the `schema_editor.connection.alias` attribute:

```
from django.db import migrations

def forwards(apps, schema_editor):
    if not schema_editor.connection.alias == 'default':
        return
    # Your migration code goes here

class Migration(migrations.Migration):

    dependencies = [
        # Dependencies to other migrations
    ]

    operations = [
```

```
migrations.RunPython(forwards),
]
```

You can also provide hints that will be passed to the `allow_migrate()` method of database routers as `**hints`:

```
myapp/dbrouters.py
```

```
class MyRouter(object):

    def allow_migrate(self, db, app_label, model_name=None, **hints):
        if 'target_db' in hints:
            return db == hints['target_db']
        return True
```

Then, to leverage this in your migrations, do the following:

```
from django.db import migrations

def forwards(apps, schema_editor):
    # Your migration code goes here
    ...

class Migration(migrations.Migration):

    dependencies = [
        # Dependencies to other migrations
    ]

    operations = [
        migrations.RunPython(forwards, hints={'target_db': 'default'}),
    ]
```

If your `RunPython` or `RunSQL` operation only affects one model, it's good practice to pass `model_name` as a hint to make it as transparent as possible to the router. This is especially important for reusable and third-party apps.

## 4.18.2 Migrations that add unique fields

Applying a “plain” migration that adds a unique non-nullable field to a table with existing rows will raise an error because the value used to populate existing rows is generated only once, thus breaking the unique constraint.

Therefore, the following steps should be taken. In this example, we'll add a non-nullable `UUIDField` with a default value. Modify the respective field according to your needs.

- Add the field on your model with `default=uuid.uuid4` and `unique=True` arguments (choose an appropriate default for the type of the field you're adding).
- Run the `makemigrations` command. This should generate a migration with an `AddField` operation.
- Generate two empty migration files for the same app by running `makemigrations myapp --empty` twice. We've renamed the migration files to give them meaningful names in the examples below.
- Copy the `AddField` operation from the auto-generated migration (the first of the three new files) to the last migration and change `AddField` to `AlterField`. For example:

```
0006_remove_uuid_null.py

# -*- coding: utf-8 -*-
# Generated by Django A.B on YYYY-MM-DD HH:MM
from __future__ import unicode_literals
```

```
from django.db import migrations, models
import uuid

class Migration(migrations.Migration):

    dependencies = [
        ('myapp', '0005_populate_uuid_values'),
    ]

    operations = [
        migrations.AlterField(
            model_name='mymodel',
            name='uuid',
            field=models.UUIDField(default=uuid.uuid4, unique=True),
        ),
    ]
```

- Edit the first migration file. The generated migration class should look similar to this:

```
0004_add_uuid_field.py
```

```
class Migration(migrations.Migration):

    dependencies = [
        ('myapp', '0003_auto_20150129_1705'),
    ]

    operations = [
        migrations.AddField(
            model_name='mymodel',
            name='uuid',
            field=models.UUIDField(default=uuid.uuid4, unique=True),
        ),
    ]
```

Change `unique=True` to `null=True` – this will create the intermediary null field and defer creating the unique constraint until we’ve populated unique values on all the rows.

- In the first empty migration file, add a [RunPython](#) or [RunSQL](#) operation to generate a unique value (UUID in the example) for each existing row. For example:

```
0005_populate_uuid_values.py
```

```
# -*- coding: utf-8 -*-
# Generated by Django A.B on YYYY-MM-DD HH:MM
from __future__ import unicode_literals

from django.db import migrations, models
import uuid

def gen_uuid(apps, schema_editor):
    MyModel = apps.get_model('myapp', 'MyModel')
    for row in MyModel.objects.all():
        row.uuid = uuid.uuid4()
        row.save()

class Migration(migrations.Migration):

    dependencies = [
        ('myapp', '0004_add_uuid_field'),
```

```

]

operations = [
    # omit reverse_code=... if you don't want the migration to be reversible.
    migrations.RunPython(gen_uuid, reverse_code=migrations.RunPython.noop),
]

```

- Now you can apply the migrations as usual with the `migrate` command.

Note there is a race condition if you allow objects to be created while this migration is running. Objects created after the `AddField` and before `RunPython` will have their original `uuid`'s overwritten.

## Non-atomic migrations

On databases that support DDL transactions (SQLite and PostgreSQL), migrations will run inside a transaction by default. For use cases such as performing data migrations on large tables, you may want to prevent a migration from running in a transaction by setting the `atomic` attribute to `False`:

```

from django.db import migrations

class Migration(migrations.Migration):
    atomic = False

```

Within such a migration, all operations are run without a transaction. It's possible to execute parts of the migration inside a transaction using `atomic()` or by passing `atomic=True` to `RunPython`.

Here's an example of a non-atomic data migration that updates a large table in smaller batches:

```

import uuid

from django.db import migrations, transaction

def gen_uuid(apps, schema_editor):
    MyModel = apps.get_model('myapp', 'MyModel')
    while MyModel.objects.filter(uuid__isnull=True).exists():
        with transaction.atomic():
            for row in MyModel.objects.filter(uuid__isnull=True)[:1000]:
                row.uuid = uuid.uuid4()
                row.save()

class Migration(migrations.Migration):
    atomic = False

    operations = [
        migrations.RunPython(gen_uuid),
    ]

```

The `atomic` attribute doesn't have an effect on databases that don't support DDL transactions (e.g. MySQL, Oracle).

### 4.18.3 Controlling the order of migrations

Django determines the order in which migrations should be applied not by the filename of each migration, but by building a graph using two properties on the `Migration` class: `dependencies` and `run_before`.

If you've used the `makemigrations` command you've probably already seen `dependencies` in action because auto-created migrations have this defined as part of their creation process.

The `dependencies` property is declared like this:

```
from django.db import migrations

class Migration(migrations.Migration):

    dependencies = [
        ('myapp', '0123_the_previous_migration'),
    ]
```

Usually this will be enough, but from time to time you may need to ensure that your migration runs *before* other migrations. This is useful, for example, to make third-party apps' migrations run *after* your `AUTH_USER_MODEL` replacement.

To achieve this, place all migrations that should depend on yours in the `run_before` attribute on your `Migration` class:

```
class Migration(migrations.Migration):
    ...

    run_before = [
        ('third_party_app', '0001_do_awesome'),
    ]
```

Prefer using `dependencies` over `run_before` when possible. You should only use `run_before` if it is undesirable or impractical to specify dependencies in the migration which you want to run after the one you are writing.

#### 4.18.4 Migrating data between third-party apps

You can use a data migration to move data from one third-party application to another.

If you plan to remove the old app later, you'll need to set the `dependencies` property based on whether or not the old app is installed. Otherwise, you'll have missing dependencies once you uninstall the old app. Similarly, you'll need to catch `LookupError` in the `apps.get_model()` call that retrieves models from the old app. This approach allows you to deploy your project anywhere without first installing and then uninstalling the old app.

Here's a sample migration:

```
myapp/migrations/0124_move_old_app_to_new_app.py

from django.apps import apps as global_apps
from django.db import migrations

def forwards(apps, schema_editor):
    try:
        OldModel = apps.get_model('old_app', 'OldModel')
    except LookupError:
        # The old app isn't installed.
        return

    NewModel = apps.get_model('new_app', 'NewModel')
    NewModel.objects.bulk_create(
        NewModel(new_attribute=old_object.old_attribute)
        for old_object in OldModel.objects.all()
    )

class Migration(migrations.Migration):
    operations = [
        migrations.RunPython(forwards, migrations.RunPython.noop),
```

```
]
dependencies = [
    ('myapp', '0123_the_previous_migration'),
    ('new_app', '0001_initial'),
]

if global_apps.is_installed('old_app'):
    dependencies.append(('old_app', '0001_initial'))
```

Also consider what you want to happen when the migration is unapplied. You could either do nothing (as in the example above) or remove some or all of the data from the new application. Adjust the second argument of the *RunPython* operation accordingly.

### 4.18.5 Changing an unmanaged model to managed

If you want to change an unmanaged model (*managed=False*) to managed, you must remove *managed=False* and generate a migration before making other schema-related changes to the model, since schema changes that appear in the migration that contains the operation to change `Meta.managed` may not be applied.

**See also:**

The [Django community aggregator](#), where we aggregate content from the global Django community. Many writers in the aggregator write this sort of how-to material.

### 5.1 FAQ: General

#### 5.1.1 Why does this project exist?

Django grew from a very practical need: World Online, a newspaper Web operation, is responsible for building intensive Web applications on journalism deadlines. In the fast-paced newsroom, World Online often has only a matter of hours to take a complicated Web application from concept to public launch.

At the same time, the World Online Web developers have consistently been perfectionists when it comes to following best practices of Web development.

In fall 2003, the World Online developers (Adrian Holovaty and Simon Willison) ditched PHP and began using Python to develop its websites. As they built intensive, richly interactive sites such as Lawrence.com, they began to extract a generic Web development framework that let them build Web applications more and more quickly. They tweaked this framework constantly, adding improvements over two years.

In summer 2005, World Online decided to open-source the resulting software, Django. Django would not be possible without a whole host of open-source projects – [Apache](#), [Python](#), and [PostgreSQL](#) to name a few – and we’re thrilled to be able to give something back to the open-source community.

#### 5.1.2 What does “Django” mean, and how do you pronounce it?

Django is named after [Django Reinhardt](#), a jazz manouche guitarist from the 1930s to early 1950s. To this day, he’s considered one of the best guitarists of all time.

Listen to his music. You’ll like it.

Django is pronounced **JANG**-oh. Rhymes with FANG-oh. The “D” is silent.

We’ve also recorded an [audio clip of the pronunciation](#).

### 5.1.3 Is Django stable?

Yes, it's quite stable. Companies like Disqus, Instagram, Pinterest, and Mozilla have been using Django for many years. Sites built on Django have weathered traffic spikes of over 50 thousand hits per second.

### 5.1.4 Does Django scale?

Yes. Compared to development time, hardware is cheap, and so Django is designed to take advantage of as much hardware as you can throw at it.

Django uses a “shared-nothing” architecture, which means you can add hardware at any level – database servers, caching servers or Web/application servers.

The framework cleanly separates components such as its database layer and application layer. And it ships with a simple-yet-powerful *cache framework*.

### 5.1.5 Who's behind this?

Django was originally developed at World Online, the Web department of a newspaper in Lawrence, Kansas, USA. Django's now run by an international *team of volunteers*.

### 5.1.6 Which sites use Django?

DjangoSites.org features a constantly growing list of Django-powered sites.

### 5.1.7 Django appears to be a MVC framework, but you call the Controller the “view”, and the View the “template”. How come you don't use the standard names?

Well, the standard names are debatable.

In our interpretation of MVC, the “view” describes the data that gets presented to the user. It's not necessarily *how* the data *looks*, but *which* data is presented. The view describes *which data you see*, not *how you see it*. It's a subtle distinction.

So, in our case, a “view” is the Python callback function for a particular URL, because that callback function describes which data is presented.

Furthermore, it's sensible to separate content from presentation – which is where templates come in. In Django, a “view” describes which data is presented, but a view normally delegates to a template, which describes *how* the data is presented.

Where does the “controller” fit in, then? In Django's case, it's probably the framework itself: the machinery that sends a request to the appropriate view, according to the Django URL configuration.

If you're hungry for acronyms, you might say that Django is a “MTV” framework – that is, “model”, “template”, and “view.” That breakdown makes much more sense.

At the end of the day, of course, it comes down to getting stuff done. And, regardless of how things are named, Django gets stuff done in a way that's most logical to us.

### 5.1.8 <Framework X> does <feature Y> – why doesn't Django?

We're well aware that there are other awesome Web frameworks out there, and we're not averse to borrowing ideas where appropriate. However, Django was developed precisely because we were unhappy with the status quo, so please be aware that “because <Framework X> does it” is not going to be sufficient reason to add a given feature to Django.

### 5.1.9 Why did you write all of Django from scratch, instead of using other Python libraries?

When Django was originally written a couple of years ago, Adrian and Simon spent quite a bit of time exploring the various Python Web frameworks available.

In our opinion, none of them were completely up to snuff.

We're picky. You might even call us perfectionists. (With deadlines.)

Over time, we stumbled across open-source libraries that did things we'd already implemented. It was reassuring to see other people solving similar problems in similar ways, but it was too late to integrate outside code: We'd already written, tested and implemented our own framework bits in several production settings – and our own code met our needs delightfully.

In most cases, however, we found that existing frameworks/tools inevitably had some sort of fundamental, fatal flaw that made us squeamish. No tool fit our philosophies 100%.

Like we said: We're picky.

We've documented our philosophies on the [design philosophies page](#).

### 5.1.10 Is Django a content-management-system (CMS)?

No, Django is not a CMS, or any sort of “turnkey product” in and of itself. It's a Web framework; it's a programming tool that lets you build websites.

For example, it doesn't make much sense to compare Django to something like [Drupal](#), because Django is something you use to *create* things like Drupal.

Of course, Django's automatic admin site is fantastic and timesaving – but the admin site is one module of Django the framework. Furthermore, although Django has special conveniences for building “CMS-y” apps, that doesn't mean it's not just as appropriate for building “non-CMS-y” apps (whatever that means!).

### 5.1.11 How can I download the Django documentation to read it offline?

The Django docs are available in the `docs` directory of each Django tarball release. These docs are in reST (reStructuredText) format, and each text file corresponds to a Web page on the official Django site.

Because the documentation is [stored in revision control](#), you can browse documentation changes just like you can browse code changes.

Technically, the docs on Django's site are generated from the latest development versions of those reST documents, so the docs on the Django site may offer more information than the docs that come with the latest Django release.

### 5.1.12 How do I cite Django?

It's difficult to give an official citation format, for two reasons: citation formats can vary wildly between publications, and citation standards for software are still a matter of some debate.

For example, [APA style](#), would dictate something like:

```
Django (Version 1.5) [Computer Software]. (2013). Retrieved from https://  
→djangoproject.com.
```

However, the only true guide is what your publisher will accept, so get a copy of those guidelines and fill in the gaps as best you can.

If your referencing style guide requires a publisher name, use “Django Software Foundation”.

If you need a publishing location, use “Lawrence, Kansas”.

If you need a web address, use <https://djangoproject.com>.

If you need a name, just use “Django”, without any tagline.

If you need a publication date, use the year of release of the version you’re referencing (e.g., 2013 for v1.5)

## 5.2 FAQ: Installation

### 5.2.1 How do I get started?

1. Download the code.
2. Install Django (read the *installation guide*).
3. Walk through the *tutorial*.
4. Check out the rest of the *documentation*, and [ask questions](#) if you run into trouble.

### 5.2.2 What are Django’s prerequisites?

Django requires Python. See the table in the next question for the versions of Python that work with each version of Django. Other Python libraries may be required for some uses, but you’ll receive an error about it as they’re needed.

For a development environment – if you just want to experiment with Django – you don’t need to have a separate Web server installed; Django comes with its own lightweight development server. For a production environment, Django follows the WSGI spec, [PEP 3333](#), which means it can run on a variety of server platforms. See [Deploying Django](#) for some popular alternatives.

If you want to use Django with a database, which is probably the case, you’ll also need a database engine. [PostgreSQL](#) is recommended, because we’re PostgreSQL fans, and [MySQL](#), [SQLite 3](#), and [Oracle](#) are also supported.

### 5.2.3 What Python version can I use with Django?

Django version	Python versions
1.8	2.7, 3.2 (until the end of 2016), 3.3, 3.4, 3.5
1.9, 1.10	2.7, 3.4, 3.5
1.11	2.7, 3.4, 3.5, 3.6
2.0	3.5+

For each version of Python, only the latest micro release (A.B.C) is officially supported. You can find the latest micro version for each series on the [Python download page](#).

Typically, we will support a Python version up to and including the first Django LTS release whose security support ends after security support for that version of Python ends. For example, Python 3.3 security support ends September

2017 and Django 1.8 LTS security support ends April 2018. Therefore Django 1.8 is the last version to support Python 3.3.

## 5.2.4 What Python version should I use with Django?

As of Django 1.6, Python 3 support is considered stable and you can safely use it in production. See also *Porting to Python 3*. However, the community is still in the process of migrating third-party packages and applications to Python 3.

If you're starting a new project, and the dependencies you plan to use work on Python 3, you should use Python 3. If they don't, consider contributing to the porting efforts, or stick to Python 2.

Since newer versions of Python are often faster, have more features, and are better supported, all else being equal, we recommend that you use the latest 2.x.y or 3.x.y release.

You don't lose anything in Django by using an older release, but you don't take advantage of the improvements and optimizations in newer Python releases. Third-party applications for use with Django are, of course, free to set their own version requirements.

## 5.2.5 Should I use the stable version or development version?

Generally, if you're using code in production, you should be using a stable release. The Django project publishes a full stable release every nine months or so, with bugfix updates in between. These stable releases contain the API that is covered by our backwards compatibility guarantees; if you write code against stable releases, you shouldn't have any problems upgrading when the next official version is released.

## 5.3 FAQ: Using Django

### 5.3.1 Why do I get an error about importing DJANGO\_SETTINGS\_MODULE?

Make sure that:

- The environment variable DJANGO\_SETTINGS\_MODULE is set to a fully-qualified Python module (i.e. "mysite.settings").
- Said module is on `sys.path` (`import mysite.settings` should work).
- The module doesn't contain syntax errors (of course).

### 5.3.2 I can't stand your template language. Do I have to use it?

We happen to think our template engine is the best thing since chunky bacon, but we recognize that choosing a template language runs close to religion. There's nothing about Django that requires using the template language, so if you're attached to Jinja2, Mako, or whatever, feel free to use those.

### 5.3.3 Do I have to use your model/database layer?

Nope. Just like the template system, the model/database layer is decoupled from the rest of the framework.

The one exception is: If you use a different database library, you won't get to use Django's automatically-generated admin site. That app is coupled to the Django database layer.

### 5.3.4 How do I use image and file fields?

Using a `FileField` or an `ImageField` in a model takes a few steps:

1. In your settings file, you'll need to define `MEDIA_ROOT` as the full path to a directory where you'd like Django to store uploaded files. (For performance, these files are not stored in the database.) Define `MEDIA_URL` as the base public URL of that directory. Make sure that this directory is writable by the Web server's user account.
2. Add the `FileField` or `ImageField` to your model, defining the `upload_to` option to specify a subdirectory of `MEDIA_ROOT` to use for uploaded files.
3. All that will be stored in your database is a path to the file (relative to `MEDIA_ROOT`). You'll most likely want to use the convenience `url` attribute provided by Django. For example, if your `ImageField` is called `mug_shot`, you can get the absolute path to your image in a template with `{{ object.mug_shot.url }}`.

### 5.3.5 How do I make a variable available to all my templates?

Sometimes your templates just all need the same thing. A common example would be dynamically-generated menus. At first glance, it seems logical to simply add a common dictionary to the template context.

The correct solution is to use a `RequestContext`. Details on how to do this are here: [Using RequestContext](#).

## 5.4 FAQ: Getting Help

### 5.4.1 How do I do X? Why doesn't Y work? Where can I go to get help?

If this FAQ doesn't contain an answer to your question, you might want to try the [django-users](#) mailing list. Feel free to ask any question related to installing, using, or debugging Django.

If you prefer IRC, the [#django IRC channel](#) on the Freenode IRC network is an active community of helpful individuals who may be able to solve your problem.

### 5.4.2 Why hasn't my message appeared on *django-users*?

[django-users](#) has a lot of subscribers. This is good for the community, as it means many people are available to contribute answers to questions. Unfortunately, it also means that [django-users](#) is an attractive target for spammers.

In order to combat the spam problem, when you join the [django-users](#) mailing list, we manually moderate the first message you send to the list. This means that spammers get caught, but it also means that your first question to the list might take a little longer to get answered. We apologize for any inconvenience that this policy may cause.

### 5.4.3 Nobody on *django-users* answered my question! What should I do?

Try making your question more specific, or provide a better example of your problem.

As with most open-source mailing lists, the folks on [django-users](#) are volunteers. If nobody has answered your question, it may be because nobody knows the answer, it may be because nobody can understand the question, or it may be that everybody that can help is busy. One thing you might try is to ask the question on IRC – visit the [#django IRC channel](#) on the Freenode IRC network.

You might notice we have a second mailing list, called [django-developers](#) – but please don't email support questions to this mailing list. This list is for discussion of the development of Django itself. Asking a tech support question there is considered quite impolite.

## 5.4.4 I think I've found a bug! What should I do?

Detailed instructions on how to handle a potential bug can be found in our *Guide to contributing to Django*.

## 5.4.5 I think I've found a security problem! What should I do?

If you think you've found a security problem with Django, please send a message to [security@djangoproject.com](mailto:security@djangoproject.com). This is a private list only open to long-time, highly trusted Django developers, and its archives are not publicly readable.

Due to the sensitive nature of security issues, we ask that if you think you have found a security problem, *please* don't send a message to one of the public mailing lists. Django has a *policy for handling security issues*; while a defect is outstanding, we would like to minimize any damage that could be inflicted through public knowledge of that defect.

## 5.5 FAQ: Databases and models

### 5.5.1 How can I see the raw SQL queries Django is running?

Make sure your Django `DEBUG` setting is set to `True`. Then, just do this:

```
>>> from django.db import connection
>>> connection.queries
[{'sql': 'SELECT polls_polls.id, polls_polls.question, polls_polls.pub_date FROM_
↪polls_polls',
'time': '0.002'}]
```

`connection.queries` is only available if `DEBUG` is `True`. It's a list of dictionaries in order of query execution. Each dictionary has the following:

```
``sql`` -- The raw SQL statement
``time`` -- How long the statement took to execute, in seconds.
```

`connection.queries` includes all SQL statements – INSERTs, UPDATES, SELECTs, etc. Each time your app hits the database, the query will be recorded.

If you are using *multiple databases*, you can use the same interface on each member of the `connections` dictionary:

```
>>> from django.db import connections
>>> connections['my_db_alias'].queries
```

If you need to clear the query list manually at any point in your functions, just call `reset_queries()`, like this:

```
from django.db import reset_queries
reset_queries()
```

### 5.5.2 Can I use Django with a pre-existing database?

Yes. See *Integrating with a legacy database*.

### 5.5.3 If I make changes to a model, how do I update the database?

Take a look at Django's support for *schema migrations*.

If you don't mind clearing data, your project's `manage.py` utility has a `flush` option to reset the database to the state it was in immediately after `migrate` was executed.

## 5.5.4 Do Django models support multiple-column primary keys?

No. Only single-column primary keys are supported.

But this isn't an issue in practice, because there's nothing stopping you from adding other constraints (using the `unique_together` model option or creating the constraint directly in your database), and enforcing the uniqueness at that level. Single-column primary keys are needed for things such as the admin interface to work; e.g., you need a simple way of being able to specify an object to edit or delete.

## 5.5.5 Does Django support NoSQL databases?

NoSQL databases are not officially supported by Django itself. There are, however, a number of side project and forks which allow NoSQL functionality in Django, like [Django non-rel](#).

You can also take a look on [the wiki page](#) which discusses some alternatives.

## 5.5.6 How do I add database-specific options to my CREATE TABLE statements, such as specifying MyISAM as the table type?

We try to avoid adding special cases in the Django code to accommodate all the database-specific options such as table type, etc. If you'd like to use any of these options, create a migration with a `RunSQL` operation that contains ALTER TABLE statements that do what you want to do.

For example, if you're using MySQL and want your tables to use the MyISAM table type, use the following SQL:

```
ALTER TABLE myapp_mytable ENGINE=MyISAM;
```

## 5.6 FAQ: The admin

### 5.6.1 I can't log in. When I enter a valid username and password, it just brings up the login page again, with no error messages.

The login cookie isn't being set correctly, because the domain of the cookie sent out by Django doesn't match the domain in your browser. Try setting the `SESSION_COOKIE_DOMAIN` setting to match your domain. For example, if you're going to "<https://www.example.com/admin/>" in your browser, set `SESSION_COOKIE_DOMAIN = 'www.example.com'`.

### 5.6.2 I can't log in. When I enter a valid username and password, it brings up the login page again, with a "Please enter a correct username and password" error.

If you're sure your username and password are correct, make sure your user account has `is_active` and `is_staff` set to True. The admin site only allows access to users with those two fields both set to True.

### 5.6.3 How do I automatically set a field’s value to the user who last edited the object in the admin?

The `ModelAdmin` class provides customization hooks that allow you to transform an object as it saved, using details from the request. By extracting the current user from the request, and customizing the `save_model()` hook, you can update an object to reflect the user that edited it. See *the documentation on ModelAdmin methods* for an example.

### 5.6.4 How do I limit admin access so that objects can only be edited by the users who created them?

The `ModelAdmin` class also provides customization hooks that allow you to control the visibility and editability of objects in the admin. Using the same trick of extracting the user from the request, the `get_queryset()` and `has_change_permission()` can be used to control the visibility and editability of objects in the admin.

### 5.6.5 My admin-site CSS and images showed up fine using the development server, but they’re not displaying when using mod\_wsgi.

See *servicing the admin files* in the “How to use Django with mod\_wsgi” documentation.

### 5.6.6 My “list\_filter” contains a ManyToManyField, but the filter doesn’t display.

Django won’t bother displaying the filter for a `ManyToManyField` if there are fewer than two related objects.

For example, if your `list_filter` includes `sites`, and there’s only one site in your database, it won’t display a “Site” filter. In that case, filtering by site would be meaningless.

### 5.6.7 Some objects aren’t appearing in the admin.

Inconsistent row counts may be caused by missing foreign key values or a foreign key field incorrectly set to `null=False`. If you have a record with a `ForeignKey` pointing to a non-existent object and that foreign key is included in `list_display`, the record will not be shown in the admin changelist because the Django model is declaring an integrity constraint that is not implemented at the database level.

### 5.6.8 How can I customize the functionality of the admin interface?

You’ve got several options. If you want to piggyback on top of an add/change form that Django automatically generates, you can attach arbitrary JavaScript modules to the page via the model’s class `Admin.js` parameter. That parameter is a list of URLs, as strings, pointing to JavaScript modules that will be included within the admin form via a `<script>` tag.

If you want more flexibility than simply tweaking the auto-generated forms, feel free to write custom views for the admin. The admin is powered by Django itself, and you can write custom views that hook into the authentication system, check permissions and do whatever else they need to do.

If you want to customize the look-and-feel of the admin interface, read the next question.

### 5.6.9 The dynamically-generated admin site is ugly! How can I change it?

We like it, but if you don't agree, you can modify the admin site's presentation by editing the CSS stylesheet and/or associated image files. The site is built using semantic HTML and plenty of CSS hooks, so any changes you'd like to make should be possible by editing the stylesheet.

### 5.6.10 What browsers are supported for using the admin?

The admin provides a fully-functional experience to YUI's A-grade browsers, with the notable exception of IE6, which is not supported.

There *may* be minor stylistic differences between supported browsers—for example, some browsers may not support rounded corners. These are considered acceptable variations in rendering.

## 5.7 FAQ: Contributing code

### 5.7.1 How can I get started contributing code to Django?

Thanks for asking! We've written an entire document devoted to this question. It's titled *Contributing to Django*.

### 5.7.2 I submitted a bug fix in the ticket system several weeks ago. Why are you ignoring my patch?

Don't worry: We're not ignoring you!

It's important to understand there is a difference between “a ticket is being ignored” and “a ticket has not been attended to yet.” Django's ticket system contains hundreds of open tickets, of various degrees of impact on end-user functionality, and Django's developers have to review and prioritize.

On top of that: the people who work on Django are all volunteers. As a result, the amount of time that we have to work on the framework is limited and will vary from week to week depending on our spare time. If we're busy, we may not be able to spend as much time on Django as we might want.

The best way to make sure tickets do not get hung up on the way to checkin is to make it dead easy, even for someone who may not be intimately familiar with that area of the code, to understand the problem and verify the fix:

- Are there clear instructions on how to reproduce the bug? If this touches a dependency (such as Pillow), a contrib module, or a specific database, are those instructions clear enough even for someone not familiar with it?
- If there are several patches attached to the ticket, is it clear what each one does, which ones can be ignored and which matter?
- Does the patch include a unit test? If not, is there a very clear explanation why not? A test expresses succinctly what the problem is, and shows that the patch actually fixes it.

If your patch stands no chance of inclusion in Django, we won't ignore it – we'll just close the ticket. So if your ticket is still open, it doesn't mean we're ignoring you; it just means we haven't had time to look at it yet.

### 5.7.3 When and how might I remind the core team of a patch I care about?

A polite, well-timed message to the mailing list is one way to get attention. To determine the right time, you need to keep an eye on the schedule. If you post your message when the core developers are trying to hit a feature deadline or

manage a planning phase, you're not going to get the sort of attention you require. However, if you draw attention to a ticket when the core developers are paying particular attention to bugs – just before a bug fixing sprint, or in the lead up to a beta release for example – you're much more likely to get a productive response.

Gentle IRC reminders can also work – again, strategically timed if possible. During a bug sprint would be a very good time, for example.

Another way to get traction is to pull several related tickets together. When the core developers sit down to fix a bug in an area they haven't touched for a while, it can take a few minutes to remember all the fine details of how that area of code works. If you collect several minor bug fixes together into a similarly themed group, you make an attractive target, as the cost of coming up to speed on an area of code can be spread over multiple tickets.

Please refrain from emailing core developers personally, or repeatedly raising the same issue over and over. This sort of behavior will not gain you any additional attention – certainly not the attention that you need in order to get your pet bug addressed.

### 5.7.4 But I've reminded you several times and you keep ignoring my patch!

Seriously - we're not ignoring you. If your patch stands no chance of inclusion in Django, we'll close the ticket. For all the other tickets, we need to prioritize our efforts, which means that some tickets will be addressed before others.

One of the criteria that is used to prioritize bug fixes is the number of people that will likely be affected by a given bug. Bugs that have the potential to affect many people will generally get priority over those that are edge cases.

Another reason that bugs might be ignored for while is if the bug is a symptom of a larger problem. While we can spend time writing, testing and applying lots of little patches, sometimes the right solution is to rebuild. If a rebuild or refactor of a particular component has been proposed or is underway, you may find that bugs affecting that component will not get as much attention. Again, this is just a matter of prioritizing scarce resources. By concentrating on the rebuild, we can close all the little bugs at once, and hopefully prevent other little bugs from appearing in the future.

Whatever the reason, please keep in mind that while you may hit a particular bug regularly, it doesn't necessarily follow that every single Django user will hit the same bug. Different users use Django in different ways, stressing different parts of the code under different conditions. When we evaluate the relative priorities, we are generally trying to consider the needs of the entire community, not just the severity for one particular user. This doesn't mean that we think your problem is unimportant – just that in the limited time we have available, we will always err on the side of making 10 people happy rather than making 1 person happy.

## 5.8 Troubleshooting

This page contains some advice about errors and problems commonly encountered during the development of Django applications.

### 5.8.1 Problems running `django-admin`

**“command not found: `django-admin`“**

`django-admin` should be on your system path if you installed Django via `python setup.py`. If it's not on your path, you can find it in `site-packages/django/bin`, where `site-packages` is a directory within your Python installation. Consider symlinking to `django-admin` from some place on your path, such as `/usr/local/bin`.

If `django-admin` doesn't work but `django-admin.py` does, you're probably using a version of Django that doesn't match the version of this documentation. `django-admin` is new in Django 1.7.

## Mac OS X permissions

If you're using Mac OS X, you may see the message “permission denied” when you try to run `django-admin`. This is because, on Unix-based systems like OS X, a file must be marked as “executable” before it can be run as a program. To do this, open Terminal.app and navigate (using the `cd` command) to the directory where *django-admin* is installed, then run the command `sudo chmod +x django-admin`.

## 5.8.2 Miscellaneous

### I'm getting a `UnicodeDecodeError`. What am I doing wrong?

This class of errors happen when a bytestring containing non-ASCII sequences is transformed into a Unicode string and the specified encoding is incorrect. The output generally looks like this:

```
UnicodeDecodeError: 'ascii' codec can't decode byte 0x?? in position ?:  
ordinal not in range(128)
```

The resolution mostly depends on the context, however here are two common pitfalls producing this error:

- Your system locale may be a default ASCII locale, like the “C” locale on UNIX-like systems (can be checked by the `locale` command). If it's the case, please refer to your system documentation to learn how you can change this to a UTF-8 locale.
- You created raw bytestrings, which is easy to do on Python 2:

```
my_string = 'café'
```

Either use the `u'` prefix or even better, add the `from __future__ import unicode_literals` line at the top of your file so that your code will be compatible with Python 3.2 which doesn't support the `u'` prefix.

Related resources:

- *Unicode in Django*
- <https://wiki.python.org/moin/UnicodeDecodeError>

## 6.1 Applications

Django contains a registry of installed applications that stores configuration and provides introspection. It also maintains a list of available *models*.

This registry is simply called *apps* and it's available in *django.apps*:

```
>>> from django.apps import apps
>>> apps.get_app_config('admin').verbose_name
'Admin'
```

### 6.1.1 Projects and applications

The term **project** describes a Django web application. The project Python package is defined primarily by a *settings* module, but it usually contains other things. For example, when you run `django-admin startproject mysite` you'll get a *mysite* project directory that contains a *mysite* Python package with *settings.py*, *urls.py*, and *wsgi.py*. The project package is often extended to include things like fixtures, CSS, and templates which aren't tied to a particular application.

A **project's root directory** (the one that contains *manage.py*) is usually the container for all of a project's applications which aren't installed separately.

The term **application** describes a Python package that provides some set of features. Applications *may be reused* in various projects.

Applications include some combination of models, views, templates, template tags, static files, URLs, middleware, etc. They're generally wired into projects with the *INSTALLED\_APPS* setting and optionally with other mechanisms such as URLconfs, the *MIDDLEWARE* setting, or template inheritance.

It is important to understand that a Django application is just a set of code that interacts with various parts of the framework. There's no such thing as an *Application* object. However, there's a few places where Django needs to interact with installed applications, mainly for configuration and also for introspection. That's why the application registry maintains metadata in an *AppConfig* instance for each installed application.

There's no restriction that a project package can't also be considered an application and have models, etc. (which would require adding it to `INSTALLED_APPS`).

## 6.1.2 Configuring applications

To configure an application, subclass `AppConfig` and put the dotted path to that subclass in `INSTALLED_APPS`.

When `INSTALLED_APPS` simply contains the dotted path to an application module, Django checks for a `default_app_config` variable in that module.

If it's defined, it's the dotted path to the `AppConfig` subclass for that application.

If there is no `default_app_config`, Django uses the base `AppConfig` class.

`default_app_config` allows applications that predate Django 1.7 such as `django.contrib.admin` to opt-in to `AppConfig` features without requiring users to update their `INSTALLED_APPS`.

New applications should avoid `default_app_config`. Instead they should require the dotted path to the appropriate `AppConfig` subclass to be configured explicitly in `INSTALLED_APPS`.

### For application authors

If you're creating a pluggable app called "Rock 'n' roll", here's how you would provide a proper name for the admin:

```
# rock_n_roll/apps.py

from django.apps import AppConfig

class RockNRollConfig(AppConfig):
    name = 'rock_n_roll'
    verbose_name = "Rock 'n' roll"
```

You can make your application load this `AppConfig` subclass by default as follows:

```
# rock_n_roll/__init__.py

default_app_config = 'rock_n_roll.apps.RockNRollConfig'
```

That will cause `RockNRollConfig` to be used when `INSTALLED_APPS` just contains `'rock_n_roll'`. This allows you to make use of `AppConfig` features without requiring your users to update their `INSTALLED_APPS` setting. Besides this use case, it's best to avoid using `default_app_config` and instead specify the app config class in `INSTALLED_APPS` as described next.

Of course, you can also tell your users to put `'rock_n_roll.apps.RockNRollConfig'` in their `INSTALLED_APPS` setting. You can even provide several different `AppConfig` subclasses with different behaviors and allow your users to choose one via their `INSTALLED_APPS` setting.

The recommended convention is to put the configuration class in a submodule of the application called `apps`. However, this isn't enforced by Django.

You must include the `name` attribute for Django to determine which application this configuration applies to. You can define any attributes documented in the `AppConfig` API reference.

---

**Note:** If your code imports the application registry in an application's `__init__.py`, the name `apps` will clash with the `apps` submodule. The best practice is to move that code to a submodule and import it. A workaround is to import the registry under a different name:

```
from django.apps import apps as django_apps
```

## For application users

If you're using “Rock 'n' roll” in a project called `anthology`, but you want it to show up as “Jazz Manouche” instead, you can provide your own configuration:

```
# anthology/apps.py

from rock_n_roll.apps import RockNRollConfig

class JazzManoucheConfig(RockNRollConfig):
    verbose_name = "Jazz Manouche"

# anthology/settings.py

INSTALLED_APPS = [
    'anthology.apps.JazzManoucheConfig',
    # ...
]
```

Again, defining project-specific configuration classes in a submodule called `apps` is a convention, not a requirement.

## 6.1.3 Application configuration

### class `AppConfig`

Application configuration objects store metadata for an application. Some attributes can be configured in `AppConfig` subclasses. Others are set by Django and read-only.

### Configurable attributes

#### `AppConfig.name`

Full Python path to the application, e.g. `'django.contrib.admin'`.

This attribute defines which application the configuration applies to. It must be set in all `AppConfig` subclasses.

It must be unique across a Django project.

#### `AppConfig.label`

Short name for the application, e.g. `'admin'`

This attribute allows relabeling an application when two applications have conflicting labels. It defaults to the last component of `name`. It should be a valid Python identifier.

It must be unique across a Django project.

#### `AppConfig.verbose_name`

Human-readable name for the application, e.g. “Administration”.

This attribute defaults to `label.title()`.

#### `AppConfig.path`

Filesystem path to the application directory, e.g.  `'/usr/lib/python3.4/dist-packages/django/contrib/admin'`.

In most cases, Django can automatically detect and set this, but you can also provide an explicit override as a class attribute on your `AppConfig` subclass. In a few situations this is required; for instance if the app package is a *namespace package* with multiple paths.

## Read-only attributes

### `AppConfig.module`

Root module for the application, e.g. `<module 'django.contrib.admin' from 'django/contrib/admin/__init__.pyc'>`.

### `AppConfig.models_module`

Module containing the models, e.g. `<module 'django.contrib.admin.models' from 'django/contrib/admin/models.pyc'>`.

It may be `None` if the application doesn't contain a `models` module. Note that the database related signals such as `pre_migrate` and `post_migrate` are only emitted for applications that have a `models` module.

## Methods

### `AppConfig.get_models()`

Returns an iterable of `Model` classes for this application.

### `AppConfig.get_model(model_name)`

Returns the `Model` with the given `model_name`. Raises `LookupError` if no such model exists in this application. `model_name` is case-insensitive.

### `AppConfig.ready()`

Subclasses can override this method to perform initialization tasks such as registering signals. It is called as soon as the registry is fully populated.

Although you can't import models at the module-level where `AppConfig` classes are defined, you can import them in `ready()`, using either an `import` statement or `get_model()`.

If you're registering *model signals*, you can refer to the sender by its string label instead of using the model class itself.

Example:

```
from django.db.models.signals import pre_save

def ready(self):
    # importing model classes
    from .models import MyModel # or...
    MyModel = self.get_model('MyModel')

    # registering signals with the model's string label
    pre_save.connect(receiver, sender='app_label.MyModel')
```

**Warning:** Although you can access model classes as described above, avoid interacting with the database in your `ready()` implementation. This includes model methods that execute queries (`save()`, `delete()`, manager methods etc.), and also raw SQL queries via `django.db.connection`. Your `ready()` method will run during startup of every management command. For example, even though the test database configuration is separate from the production settings, `manage.py test` would still execute some queries against your **production** database!

---

**Note:** In the usual initialization process, the `ready` method is only called once by Django. But in some corner cases, particularly in tests which are fiddling with installed applications, `ready` might be called more than once. In that case, either write idempotent methods, or put a flag on your `AppConfig` classes to prevent re-running code which should be executed exactly one time.

---

## Namespace packages as apps (Python 3.3+)

Python versions 3.3 and later support Python packages without an `__init__.py` file. These packages are known as “namespace packages” and may be spread across multiple directories at different locations on `sys.path` (see [PEP 420](#)).

Django applications require a single base filesystem path where Django (depending on configuration) will search for templates, static assets, etc. Thus, namespace packages may only be Django applications if one of the following is true:

1. The namespace package actually has only a single location (i.e. is not spread across more than one directory.)
2. The `AppConfig` class used to configure the application has a `path` class attribute, which is the absolute directory path Django will use as the single base path for the application.

If neither of these conditions is met, Django will raise `ImproperlyConfigured`.

## 6.1.4 Application registry

### apps

The application registry provides the following public API. Methods that aren’t listed below are considered private and may change without notice.

#### `apps.ready`

Boolean attribute that is set to `True` after the registry is fully populated and all `AppConfig.ready()` methods are called.

#### `apps.get_app_configs()`

Returns an iterable of `AppConfig` instances.

#### `apps.get_app_config(app_label)`

Returns an `AppConfig` for the application with the given `app_label`. Raises `LookupError` if no such application exists.

#### `apps.is_installed(app_name)`

Checks whether an application with the given name exists in the registry. `app_name` is the full name of the app, e.g. `'django.contrib.admin'`.

#### `apps.get_model(app_label, model_name)`

Returns the `Model` with the given `app_label` and `model_name`. As a shortcut, this method also accepts a single argument in the form `app_label.model_name`. `model_name` is case-insensitive.

Raises `LookupError` if no such application or model exists. Raises `ValueError` when called with a single argument that doesn’t contain exactly one dot.

## 6.1.5 Initialization process

### How applications are loaded

When Django starts, `django.setup()` is responsible for populating the application registry.

**setup** (*set\_prefix=True*)

Configures Django by:

- Loading the settings.
- Setting up logging.
- If `set_prefix` is `True`, setting the URL resolver script prefix to `FORCE_SCRIPT_NAME` if defined, or `/` otherwise.
- Initializing the application registry.

The ability to set the URL resolver script prefix is new.

This function is called automatically:

- When running an HTTP server via Django's WSGI support.
- When invoking a management command.

It must be called explicitly in other cases, for instance in plain Python scripts.

The application registry is initialized in three stages. At each stage, Django processes all applications in the order of `INSTALLED_APPS`.

1. First Django imports each item in `INSTALLED_APPS`.

If it's an application configuration class, Django imports the root package of the application, defined by its `name` attribute. If it's a Python package, Django creates a default application configuration.

*At this stage, your code shouldn't import any models!*

In other words, your applications' root packages and the modules that define your application configuration classes shouldn't import any models, even indirectly.

Strictly speaking, Django allows importing models once their application configuration is loaded. However, in order to avoid needless constraints on the order of `INSTALLED_APPS`, it's strongly recommended not import any models at this stage.

Once this stage completes, APIs that operate on application configurations such as `get_app_config()` become usable.

2. Then Django attempts to import the `models` submodule of each application, if there is one.

You must define or import all models in your application's `models.py` or `models/__init__.py`. Otherwise, the application registry may not be fully populated at this point, which could cause the ORM to malfunction.

Once this stage completes, APIs that operate on models such as `get_model()` become usable.

3. Finally Django runs the `ready()` method of each application configuration.

### Troubleshooting

Here are some common problems that you may encounter during initialization:

- `AppRegistryNotReady`: This happens when importing an application configuration or a models module triggers code that depends on the app registry.

For example, `ugettext()` uses the app registry to look up translation catalogs in applications. To translate at import time, you need `ugettext_lazy()` instead. (Using `ugettext()` would be a bug, because the translation would happen at import time, rather than at each request depending on the active language.)

Executing database queries with the ORM at import time in models modules will also trigger this exception. The ORM cannot function properly until all models are available.

Another common culprit is `django.contrib.auth.get_user_model()`. Use the `AUTH_USER_MODEL` setting to reference the User model at import time.

This exception also happens if you forget to call `django.setup()` in a standalone Python script.

- `ImportError: cannot import name ...` This happens if the import sequence ends up in a loop. To eliminate such problems, you should minimize dependencies between your models modules and do as little work as possible at import time. To avoid executing code at import time, you can move it into a function and cache its results. The code will be executed when you first need its results. This concept is known as “lazy evaluation”.
- `django.contrib.admin` automatically performs autodiscovery of admin modules in installed applications. To prevent it, change your `INSTALLED_APPS` to contain `'django.contrib.admin.apps.SimpleAdminConfig'` instead of `'django.contrib.admin'`.

## 6.2 System check framework

The system check framework is a set of static checks for validating Django projects. It detects common problems and provides hints for how to fix them. The framework is extensible so you can easily add your own checks.

For details on how to add your own checks and integrate them with Django’s system checks, see the [System check topic guide](#).

### 6.2.1 API Reference

#### CheckMessage

**class CheckMessage** (*level, msg, hint=None, obj=None, id=None*)

The warnings and errors raised by system checks must be instances of `CheckMessage`. An instance encapsulates a single reportable error or warning. It also provides context and hints applicable to the message, and a unique identifier that is used for filtering purposes.

Constructor arguments are:

**level** The severity of the message. Use one of the predefined values: `DEBUG`, `INFO`, `WARNING`, `ERROR`, `CRITICAL`. If the level is greater or equal to `ERROR`, then Django will prevent management commands from executing. Messages with level lower than `ERROR` (i.e. warnings) are reported to the console, but can be silenced.

**msg** A short (less than 80 characters) string describing the problem. The string should *not* contain newlines.

**hint** A single-line string providing a hint for fixing the problem. If no hint can be provided, or the hint is self-evident from the error message, the hint can be omitted, or a value of `None` can be used.

**obj** Optional. An object providing context for the message (for example, the model where the problem was discovered). The object should be a model, field, or manager or any other object that defines `__str__` method (on

Python 2 you need to define `__unicode__` method). The method is used while reporting all messages and its result precedes the message.

**id** Optional string. A unique identifier for the issue. Identifiers should follow the pattern `app_label.X001`, where X is one of the letters CEWID, indicating the message severity (C for criticals, E for errors and so). The number can be allocated by the application, but should be unique within that application.

There are subclasses to make creating messages with common levels easier. When using them you can omit the `level` argument because it is implied by the class name.

```
class Debug(msg, hint=None, obj=None, id=None)
```

```
class Info(msg, hint=None, obj=None, id=None)
```

```
class Warning(msg, hint=None, obj=None, id=None)
```

```
class Error(msg, hint=None, obj=None, id=None)
```

```
class Critical(msg, hint=None, obj=None, id=None)
```

## 6.2.2 Builtin checks

### Builtin tags

Django's system checks are organized using the following tags:

- **models**: Checks governing model, field and manager definitions.
- **signals**: Checks on signal declarations and handler registrations.
- **admin**: Checks of any admin site declarations.
- **compatibility**: Flagging potential problems with version upgrades.
- **security**: Checks security related configuration.
- **templates**: Checks template related configuration.
- **caches**: Checks cache related configuration.
- **urls**: Checks URL configuration.
- **database**: Checks database-related configuration issues. Database checks are not run by default because they do more than static code analysis as regular checks do. They are only run by the `migrate` command or if you specify the `database` tag when calling the `check` command.

The `database` tag was added.

Some checks may be registered with multiple tags.

### Core system checks

#### Models

- **models.E001**: `<swappable>` is not of the form `app_label.app_name`.
- **models.E002**: `<SETTING>` references `<model>`, which has not been installed, or is abstract.
- **models.E003**: The model has two many-to-many relations through the intermediate model `<app_label>`. `<model>`.
- **models.E004**: `id` can only be used as a field name if the field also sets `primary_key=True`.

- **models.E005:** The field `<field name>` from parent model `<model>` clashes with the field `<field name>` from parent model `<model>`.
- **models.E006:** The field clashes with the field `<field name>` from model `<model>`.
- **models.E007:** Field `<field name>` has column name `<column name>` that is used by another field.
- **models.E008:** `index_together` must be a list or tuple.
- **models.E009:** All `index_together` elements must be lists or tuples.
- **models.E010:** `unique_together` must be a list or tuple.
- **models.E011:** All `unique_together` elements must be lists or tuples.
- **models.E012:** `index_together/unique_together` refers to the non-existent field `<field name>`.
- **models.E013:** `index_together/unique_together` refers to a `ManyToManyField` `<field name>`, but `ManyToManyFields` are not supported for that option.
- **models.E014:** `ordering` must be a tuple or list (even if you want to order by only one field).
- **models.E015:** `ordering` refers to the non-existent field `<field name>`.
- **models.E016:** `index_together/unique_together` refers to field `<field_name>` which is not local to model `<model>`.
- **models.E017:** Proxy model `<model>` contains model fields.
- **models.E018:** Autogenerated column name too long for field `<field>`. Maximum length is `<maximum length>` for database `<alias>`.
- **models.E019:** Autogenerated column name too long for M2M field `<M2M field>`. Maximum length is `<maximum length>` for database `<alias>`.
- **models.E020:** The `<model>.check()` class method is currently overridden.
- **models.E021:** `ordering` and `order_with_respect_to` cannot be used together.
- **models.E022:** `<function>` contains a lazy reference to `<app label>.<model>`, but app `<app label>` isn't installed or doesn't provide model `<model>`.

## Fields

- **fields.E001:** Field names must not end with an underscore.
- **fields.E002:** Field names must not contain `"__"`.
- **fields.E003:** `pk` is a reserved word that cannot be used as a field name.
- **fields.E004:** `choices` must be an iterable (e.g., a list or tuple).
- **fields.E005:** `choices` must be an iterable returning (actual value, human readable name) tuples.
- **fields.E006:** `db_index` must be `None`, `True` or `False`.
- **fields.E007:** Primary keys must not have `null=True`.
- **fields.E100:** `AutoFields` must set `primary_key=True`.
- **fields.E110:** `BooleanFields` do not accept null values.
- **fields.E120:** `CharFields` must define a `max_length` attribute.
- **fields.E121:** `max_length` must be a positive integer.

- **fields.W122:** `max_length` is ignored when used with `IntegerField`.
- **fields.E130:** `DecimalFields` must define a `decimal_places` attribute.
- **fields.E131:** `decimal_places` must be a non-negative integer.
- **fields.E132:** `DecimalFields` must define a `max_digits` attribute.
- **fields.E133:** `max_digits` must be a non-negative integer.
- **fields.E134:** `max_digits` must be greater or equal to `decimal_places`.
- **fields.E140:** `FilePathFields` must have either `allow_files` or `allow_folders` set to `True`.
- **fields.E150:** `GenericIPAddressFields` cannot accept blank values if null values are not allowed, as blank values are stored as nulls.
- **fields.E160:** The options `auto_now`, `auto_now_add`, and `default` are mutually exclusive. Only one of these options may be present.
- **fields.W161:** Fixed default value provided.
- **fields.E900:** `IPAddressField` has been removed except for support in historical migrations.
- **fields.W900:** `IPAddressField` has been deprecated. Support for it (except in historical migrations) will be removed in Django 1.9. *This check appeared in Django 1.7 and 1.8.*
- **fields.W901:** `CommaSeparatedIntegerField` has been deprecated. Support for it (except in historical migrations) will be removed in Django 2.0.

## File Fields

- **fields.E200:** `unique` is not a valid argument for a `FileField`.
- **fields.E201:** `primary_key` is not a valid argument for a `FileField`.
- **fields.E210:** Cannot use `ImageField` because `Pillow` is not installed.

## Related Fields

- **fields.E300:** Field defines a relation with model `<model>`, which is either not installed, or is abstract.
- **fields.E301:** Field defines a relation with the model `<model>` which has been swapped out.
- **fields.E302:** Accessor for field `<field name>` clashes with field `<field name>`.
- **fields.E303:** Reverse query name for field `<field name>` clashes with field `<field name>`.
- **fields.E304:** Field name `<field name>` clashes with accessor for `<field name>`.
- **fields.E305:** Field name `<field name>` clashes with reverse query name for `<field name>`.
- **fields.E306:** Related name must be a valid Python identifier or end with a `'+'`.
- **fields.E307:** The field `<app label>.<model>.<field name>` was declared with a lazy reference to `<app label>.<model>`, but `app <app label>` isn't installed or doesn't provide model `<model>`.
- **fields.E310:** No subset of the fields `<field1>`, `<field2>`, ... on model `<model>` is unique. Add `unique=True` on any of those fields or add at least a subset of them to a `unique_together` constraint.
- **fields.E311:** `<model>` must set `unique=True` because it is referenced by a `ForeignKey`.
- **fields.E320:** Field specifies `on_delete=SET_NULL`, but cannot be null.

- **fields.E321:** The field specifies `on_delete=SET_DEFAULT`, but has no default value.
- **fields.E330:** `ManyToManyFields` cannot be unique.
- **fields.E331:** Field specifies a many-to-many relation through model `<model>`, which has not been installed.
- **fields.E332:** Many-to-many fields with intermediate tables must not be symmetrical.
- **fields.E333:** The model is used as an intermediate model by `<model>`, but it has more than two foreign keys to `<model>`, which is ambiguous. You must specify which two foreign keys Django should use via the `through_fields` keyword argument.
- **fields.E334:** The model is used as an intermediate model by `<model>`, but it has more than one foreign key from `<model>`, which is ambiguous. You must specify which foreign key Django should use via the `through_fields` keyword argument.
- **fields.E335:** The model is used as an intermediate model by `<model>`, but it has more than one foreign key to `<model>`, which is ambiguous. You must specify which foreign key Django should use via the `through_fields` keyword argument.
- **fields.E336:** The model is used as an intermediary model by `<model>`, but it does not have foreign key to `<model>` or `<model>`.
- **fields.E337:** Field specifies `through_fields` but does not provide the names of the two link fields that should be used for the relation through `<model>`.
- **fields.E338:** The intermediary model `<through model>` has no field `<field name>`.
- **fields.E339:** `<model>.<field name>` is not a foreign key to `<model>`.
- **fields.W340:** `null` has no effect on `ManyToManyField`.
- **fields.W341:** `ManyToManyField` does not support validators.
- **fields.W342:** Setting `unique=True` on a `ForeignKey` has the same effect as using a `OneToOneField`.

## Signals

- **signals.E001:** `<handler>` was connected to the `<signal>` signal with a lazy reference to the sender `<app label>.<model>`, but `app <app label>` isn't installed or doesn't provide `model <model>`.

## Backwards Compatibility

The following checks are performed to warn the user of any potential problems that might occur as a result of a version upgrade.

- **1\_6.W001:** Some project unit tests may not execute as expected. *This check was removed in Django 1.8 due to false positives.*
- **1\_6.W002:** `BooleanField` does not have a default value. *This check was removed in Django 1.8 due to false positives.*
- **1\_7.W001:** Django 1.7 changed the global defaults for the `MIDDLEWARE_CLASSES`. `django.contrib.sessions.middleware.SessionMiddleware`, `django.contrib.auth.middleware.AuthenticationMiddleware`, and `django.contrib.messages.middleware.MessageMiddleware` were removed from the defaults. If your project needs these middleware then you should configure this setting. *This check was removed in Django 1.9.*
- **1\_8.W001:** The standalone `TEMPLATE_*` settings were deprecated in Django 1.8 and the `TEMPLATES` dictionary takes precedence. You must put the values of the following settings into your defaults `TEMPLATES` dict:

TEMPLATE\_DIRS, TEMPLATE\_CONTEXT\_PROCESSORS, TEMPLATE\_DEBUG, TEMPLATE\_LOADERS, TEMPLATE\_STRING\_IF\_INVALID.

- **1.10.W001:** The `MIDDLEWARE_CLASSES` setting is deprecated in Django 1.10 and the `MIDDLEWARE` setting takes precedence. Since you've set `MIDDLEWARE`, the value of `MIDDLEWARE_CLASSES` is ignored.

## Admin

Admin checks are all performed as part of the `admin` tag.

The following checks are performed on any `ModelAdmin` (or subclass) that is registered with the admin site:

- **admin.E001:** The value of `raw_id_fields` must be a list or tuple.
- **admin.E002:** The value of `raw_id_fields[n]` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E003:** The value of `raw_id_fields[n]` must be a foreign key or a many-to-many field.
- **admin.E004:** The value of `fields` must be a list or tuple.
- **admin.E005:** Both `fieldsets` and `fields` are specified.
- **admin.E006:** The value of `fields` contains duplicate field(s).
- **admin.E007:** The value of `fieldsets` must be a list or tuple.
- **admin.E008:** The value of `fieldsets[n]` must be a list or tuple.
- **admin.E009:** The value of `fieldsets[n]` must be of length 2.
- **admin.E010:** The value of `fieldsets[n][1]` must be a dictionary.
- **admin.E011:** The value of `fieldsets[n][1]` must contain the key `fields`.
- **admin.E012:** There are duplicate field(s) in `fieldsets[n][1]`.
- **admin.E013:** `fields[n]/fieldsets[n][m]` cannot include the `ManyToManyField` `<field name>`, because that field manually specifies a relationship model.
- **admin.E014:** The value of `exclude` must be a list or tuple.
- **admin.E015:** The value of `exclude` contains duplicate field(s).
- **admin.E016:** The value of `form` must inherit from `BaseModelForm`.
- **admin.E017:** The value of `filter_vertical` must be a list or tuple.
- **admin.E018:** The value of `filter_horizontal` must be a list or tuple.
- **admin.E019:** The value of `filter_vertical[n]/filter_vertical[n]` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E020:** The value of `filter_vertical[n]/filter_vertical[n]` must be a many-to-many field.
- **admin.E021:** The value of `radio_fields` must be a dictionary.
- **admin.E022:** The value of `radio_fields` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E023:** The value of `radio_fields` refers to `<field name>`, which is not a `ForeignKey`, and does not have a `choices` definition.
- **admin.E024:** The value of `radio_fields[<field name>]` must be either `admin.HORIZONTAL` or `admin.VERTICAL`.
- **admin.E025:** The value of `view_on_site` must be either a callable or a boolean value.

- **admin.E026:** The value of `prepopulated_fields` must be a dictionary.
- **admin.E027:** The value of `prepopulated_fields` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E028:** The value of `prepopulated_fields` refers to `<field name>`, which must not be a `DateTimeField`, a `ForeignKey`, or a `ManyToManyField` field.
- **admin.E029:** The value of `prepopulated_fields[<field name>]` must be a list or tuple.
- **admin.E030:** The value of `prepopulated_fields` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E031:** The value of `ordering` must be a list or tuple.
- **admin.E032:** The value of `ordering` has the random ordering marker `?`, but contains other fields as well.
- **admin.E033:** The value of `ordering` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E034:** The value of `readonly_fields` must be a list or tuple.
- **admin.E035:** The value of `readonly_fields[n]` is not a callable, an attribute of `<ModelAdmin class>`, or an attribute of `<model>`.

### ModelAdmin

The following checks are performed on any *ModelAdmin* that is registered with the admin site:

- **admin.E101:** The value of `save_as` must be a boolean.
- **admin.E102:** The value of `save_on_top` must be a boolean.
- **admin.E103:** The value of `inlines` must be a list or tuple.
- **admin.E104:** `<InlineModelAdmin class>` must inherit from `BaseModelAdmin`.
- **admin.E105:** `<InlineModelAdmin class>` must have a `model` attribute.
- **admin.E106:** The value of `<InlineModelAdmin class>.model` must be a `Model`.
- **admin.E107:** The value of `list_display` must be a list or tuple.
- **admin.E108:** The value of `list_display[n]` refers to `<label>`, which is not a callable, an attribute of `<ModelAdmin class>`, or an attribute or method on `<model>`.
- **admin.E109:** The value of `list_display[n]` must not be a `ManyToManyField` field.
- **admin.E110:** The value of `list_display_links` must be a list, a tuple, or `None`.
- **admin.E111:** The value of `list_display_links[n]` refers to `<label>`, which is not defined in `list_display`.
- **admin.E112:** The value of `list_filter` must be a list or tuple.
- **admin.E113:** The value of `list_filter[n]` must inherit from `ListFilter`.
- **admin.E114:** The value of `list_filter[n]` must not inherit from `FieldListFilter`.
- **admin.E115:** The value of `list_filter[n][1]` must inherit from `FieldListFilter`.
- **admin.E116:** The value of `list_filter[n]` refers to `<label>`, which does not refer to a `Field`.
- **admin.E117:** The value of `list_select_related` must be a boolean, tuple or list.
- **admin.E118:** The value of `list_per_page` must be an integer.
- **admin.E119:** The value of `list_max_show_all` must be an integer.

- **admin.E120:** The value of `list_editable` must be a list or tuple.
- **admin.E121:** The value of `list_editable[n]` refers to `<label>`, which is not an attribute of `<model>`.
- **admin.E122:** The value of `list_editable[n]` refers to `<label>`, which is not contained in `list_display`.
- **admin.E123:** The value of `list_editable[n]` cannot be in both `list_editable` and `list_display_links`.
- **admin.E124:** The value of `list_editable[n]` refers to the first field in `list_display` (`<label>`), which cannot be used unless `list_display_links` is set.
- **admin.E125:** The value of `list_editable[n]` refers to `<field name>`, which is not editable through the admin.
- **admin.E126:** The value of `search_fields` must be a list or tuple.
- **admin.E127:** The value of `date_hierarchy` refers to `<field name>`, which is not an attribute of `<model>`.
- **admin.E128:** The value of `date_hierarchy` must be a `DateField` or `DateTimeField`.

### InlineModelAdmin

The following checks are performed on any *InlineModelAdmin* that is registered as an inline on a *ModelAdmin*.

- **admin.E201:** Cannot exclude the field `<field name>`, because it is the foreign key to the parent model `<app_label>.<model>`.
- **admin.E202:** `<model>` has no `ForeignKey` to `<parent model>`./ `<model>` has more than one `ForeignKey` to `<parent model>`.
- **admin.E203:** The value of `extra` must be an integer.
- **admin.E204:** The value of `max_num` must be an integer.
- **admin.E205:** The value of `min_num` must be an integer.
- **admin.E206:** The value of `formset` must inherit from `BaseModelFormSet`.

### GenericInlineModelAdmin

The following checks are performed on any *GenericInlineModelAdmin* that is registered as an inline on a *ModelAdmin*.

- **admin.E301:** `'ct_field'` references `<label>`, which is not a field on `<model>`.
- **admin.E302:** `'ct_fk_field'` references `<label>`, which is not a field on `<model>`.
- **admin.E303:** `<model>` has no `GenericForeignKey`.
- **admin.E304:** `<model>` has no `GenericForeignKey` using content type field `<field name>` and object ID field `<field name>`.

### AdminSite

The following checks are performed on the default *AdminSite*:

- **admin.E401:** `django.contrib.contenttypes` must be in `INSTALLED_APPS` in order to use the admin application.
- **admin.E402:** `django.contrib.auth.context_processors.auth` must be in `TEMPLATES` in order to use the admin application.

## Auth

- **auth.E001:** `REQUIRED_FIELDS` must be a list or tuple.
- **auth.E002:** The field named as the `USERNAME_FIELD` for a custom user model must not be included in `REQUIRED_FIELDS`.
- **auth.E003:** `<field>` must be unique because it is named as the `USERNAME_FIELD`.
- **auth.W004:** `<field>` is named as the `USERNAME_FIELD`, but it is not unique.
- **auth.E005:** The permission codenamed `<codename>` clashes with a builtin permission for model `<model>`.
- **auth.E006:** The permission codenamed `<codename>` is duplicated for model `<model>`.
- **auth.E007:** The `verbose_name` of model `<model>` must be at most 244 characters for its builtin permission names to be at most 255 characters.
- **auth.E008:** The permission named `<name>` of model `<model>` is longer than 255 characters.
- **auth.C009:** `<User model>.is_anonymous` must be an attribute or property rather than a method. Ignoring this is a security issue as anonymous users will be treated as authenticated!
- **auth.C010:** `<User model>.is_authenticated` must be an attribute or property rather than a method. Ignoring this is a security issue as anonymous users will be treated as authenticated!

## Content Types

The following checks are performed when a model contains a `GenericForeignKey` or `GenericRelation`:

- **contenttypes.E001:** The `GenericForeignKey` object ID references the non-existent field `<field>`.
- **contenttypes.E002:** The `GenericForeignKey` content type references the non-existent field `<field>`.
- **contenttypes.E003:** `<field>` is not a `ForeignKey`.
- **contenttypes.E004:** `<field>` is not a `ForeignKey` to `contenttypes.ContentType`.

## Security

The security checks do not make your site secure. They do not audit code, do intrusion detection, or do anything particularly complex. Rather, they help perform an automated, low-hanging-fruit checklist. They help you remember the simple things that improve your site's security.

Some of these checks may not be appropriate for your particular deployment configuration. For instance, if you do your HTTP to HTTPS redirection in a load balancer, it'd be irritating to be constantly warned about not having enabled `SECURE_SSL_REDIRECT`. Use `SILENCED_SYSTEM_CHECKS` to silence unneeded checks.

The following checks are run if you use the `check --deploy` option:

- **security.W001:** You do not have `django.middleware.security.SecurityMiddleware` in your `MIDDLEWARE/MIDDLEWARE_CLASSES` so the `SECURE_HSTS_SECONDS`, `SECURE_CONTENT_TYPE_NOSNIFF`, `SECURE_BROWSER_XSS_FILTER`, and `SECURE_SSL_REDIRECT` settings will have no effect.

- **security.W002:** You do not have `django.middleware.clickjacking.XFrameOptionsMiddleware` in your `MIDDLEWARE/MIDDLEWARE_CLASSES`, so your pages will not be served with an 'x-frame-options' header. Unless there is a good reason for your site to be served in a frame, you should consider enabling this header to help prevent clickjacking attacks.
- **security.W003:** You don't appear to be using Django's built-in cross-site request forgery protection via the middleware (`django.middleware.csrf.CsrfViewMiddleware` is not in your `MIDDLEWARE/MIDDLEWARE_CLASSES`). Enabling the middleware is the safest approach to ensure you don't leave any holes.
- **security.W004:** You have not set a value for the `SECURE_HSTS_SECONDS` setting. If your entire site is served only over SSL, you may want to consider setting a value and enabling `HTTP Strict Transport Security`. Be sure to read the documentation first; enabling HSTS carelessly can cause serious, irreversible problems.
- **security.W005:** You have not set the `SECURE_HSTS_INCLUDE_SUBDOMAINS` setting to `True`. Without this, your site is potentially vulnerable to attack via an insecure connection to a subdomain. Only set this to `True` if you are certain that all subdomains of your domain should be served exclusively via SSL.
- **security.W006:** Your `SECURE_CONTENT_TYPE_NOSNIFF` setting is not set to `True`, so your pages will not be served with an 'x-content-type-options: nosniff' header. You should consider enabling this header to prevent the browser from identifying content types incorrectly.
- **security.W007:** Your `SECURE_BROWSER_XSS_FILTER` setting is not set to `True`, so your pages will not be served with an 'x-xss-protection: 1; mode=block' header. You should consider enabling this header to activate the browser's XSS filtering and help prevent XSS attacks.
- **security.W008:** Your `SECURE_SSL_REDIRECT` setting is not set to `True`. Unless your site should be available over both SSL and non-SSL connections, you may want to either set this setting to `True` or configure a load balancer or reverse-proxy server to redirect all connections to HTTPS.
- **security.W009:** Your `SECRET_KEY` has less than 50 characters or less than 5 unique characters. Please generate a long and random `SECRET_KEY`, otherwise many of Django's security-critical features will be vulnerable to attack.
- **security.W010:** You have `django.contrib.sessions` in your `INSTALLED_APPS` but you have not set `SESSION_COOKIE_SECURE` to `True`. Using a secure-only session cookie makes it more difficult for network traffic sniffers to hijack user sessions.
- **security.W011:** You have `django.contrib.sessions.middleware.SessionMiddleware` in your `MIDDLEWARE/MIDDLEWARE_CLASSES`, but you have not set `SESSION_COOKIE_SECURE` to `True`. Using a secure-only session cookie makes it more difficult for network traffic sniffers to hijack user sessions.
- **security.W012:** `SESSION_COOKIE_SECURE` is not set to `True`. Using a secure-only session cookie makes it more difficult for network traffic sniffers to hijack user sessions.
- **security.W013:** You have `django.contrib.sessions` in your `INSTALLED_APPS`, but you have not set `SESSION_COOKIE_HTTPONLY` to `True`. Using an `HttpOnly` session cookie makes it more difficult for cross-site scripting attacks to hijack user sessions.
- **security.W014:** You have `django.contrib.sessions.middleware.SessionMiddleware` in your `MIDDLEWARE/MIDDLEWARE_CLASSES`, but you have not set `SESSION_COOKIE_HTTPONLY` to `True`. Using an `HttpOnly` session cookie makes it more difficult for cross-site scripting attacks to hijack user sessions.
- **security.W015:** `SESSION_COOKIE_HTTPONLY` is not set to `True`. Using an `HttpOnly` session cookie makes it more difficult for cross-site scripting attacks to hijack user sessions.
- **security.W016:** `CSRF_COOKIE_SECURE` is not set to `True`. Using a secure-only CSRF cookie makes it more difficult for network traffic sniffers to steal the CSRF token.

- **security.W017:** `CSRF_COOKIE_HTTPONLY` is not set to `True`. Using an `HttpOnly` CSRF cookie makes it more difficult for cross-site scripting attacks to steal the CSRF token.
- **security.W018:** You should not have `DEBUG` set to `True` in deployment.
- **security.W019:** You have `django.middleware.clickjacking.XFrameOptionsMiddleware` in your `MIDDLEWARE/MIDDLEWARE_CLASSES`, but `X_FRAME_OPTIONS` is not set to `'DENY'`. The default is `'SAMEORIGIN'`, but unless there is a good reason for your site to serve other parts of itself in a frame, you should change it to `'DENY'`.
- **security.W020:** `ALLOWED_HOSTS` must not be empty in deployment.

## Sites

The following checks are performed on any model using a `CurrentSiteManager`:

- **sites.E001:** `CurrentSiteManager` could not find a field named `<field name>`.
- **sites.E002:** `CurrentSiteManager` cannot use `<field>` as it is not a foreign key or a many-to-many field.

## Database

### MySQL

If you're using MySQL, the following checks will be performed:

- **mysql.E001:** MySQL does not allow unique `CharFields` to have a `max_length > 255`.
- **mysql.W002:** MySQL Strict Mode is not set for database connection `'<alias>'`. See also *Setting sql\_mode*.

## Templates

The following checks verify that your `TEMPLATES` setting is correctly configured:

- **templates.E001:** You have `'APP_DIRS': True` in your `TEMPLATES` but also specify `'loaders'` in `OPTIONS`. Either remove `APP_DIRS` or remove the `'loaders'` option.
- **templates.E002:** `string_if_invalid` in `TEMPLATES OPTIONS` must be a string but got: `{value}` (`{type}`).

## Caches

The following checks verify that your `CACHES` setting is correctly configured:

- **caches.E001:** You must define a `'default'` cache in your `CACHES` setting.

## URLs

The following checks are performed on your URL configuration:

- **urls.W001:** Your URL pattern `<pattern>` uses `include()` with a `regex` ending with a `$`. Remove the dollar from the `regex` to avoid problems including URLs.
- **urls.W002:** Your URL pattern `<pattern>` has a `regex` beginning with a `/`. Remove this slash as it is unnecessary. If this pattern is targeted in an `include()`, ensure the `include()` pattern has a trailing `/`.

- **urls.W003:** Your URL pattern <pattern> has a name including a `:`. Remove the colon, to avoid ambiguous namespace references.
- **urls.E004:** Your URL pattern <pattern> is invalid. Ensure that `urlpatterns` is a list of `url()` instances.

## 6.3 Built-in class-based views API

Class-based views API reference. For introductory material, see the *Class-based views* topic guide.

### 6.3.1 Base views

The following three classes provide much of the functionality needed to create Django views. You may think of them as *parent* views, which can be used by themselves or inherited from. They may not provide all the capabilities required for projects, in which case there are Mixins and Generic class-based views.

Many of Django's built-in class-based views inherit from other class-based views or various mixins. Because this inheritance chain is very important, the ancestor classes are documented under the section title of **Ancestors (MRO)**. MRO is an acronym for Method Resolution Order.

#### View

**class** `django.views.generic.base.View`

The master class-based base view. All other class-based views inherit from this base class. It isn't strictly a generic view and thus can also be imported from `django.views`.

The ability to import from `django.views` was added.

#### Method Flowchart

1. `dispatch()`
2. `http_method_not_allowed()`
3. `options()`

#### Example `views.py`:

```
from django.http import HttpResponse
from django.views import View

class MyView(View):

    def get(self, request, *args, **kwargs):
        return HttpResponse('Hello, World!')
```

#### Example `urls.py`:

```
from django.conf.urls import url

from myapp.views import MyView

urlpatterns = [
    url(r'^mine/$', MyView.as_view(), name='my-view'),
]
```

#### Attributes

**http\_method\_names**

The list of HTTP method names that this view will accept.

Default:

```
['get', 'post', 'put', 'patch', 'delete', 'head', 'options', 'trace']
```

**Methods****classmethod as\_view** (*\*\*initkwargs*)

Returns a callable view that takes a request and returns a response:

```
response = MyView.as_view()(request)
```

The returned view has `view_class` and `view_initkwargs` attributes.

**dispatch** (*request, \*args, \*\*kwargs*)

The `view` part of the view – the method that accepts a `request` argument plus arguments, and returns a HTTP response.

The default implementation will inspect the HTTP method and attempt to delegate to a method that matches the HTTP method; a GET will be delegated to `get()`, a POST to `post()`, and so on.

By default, a HEAD request will be delegated to `get()`. If you need to handle HEAD requests in a different way than GET, you can override the `head()` method. See [Supporting other HTTP methods](#) for an example.

**http\_method\_not\_allowed** (*request, \*args, \*\*kwargs*)

If the view was called with a HTTP method it doesn't support, this method is called instead.

The default implementation returns `HttpResponseNotAllowed` with a list of allowed methods in plain text.

**options** (*request, \*args, \*\*kwargs*)

Handles responding to requests for the OPTIONS HTTP verb. Returns a response with the `Allow` header containing a list of the view's allowed HTTP method names.

**TemplateView****class** `django.views.generic.base.TemplateView`

Renders a given template, with the context containing parameters captured in the URL.

**Ancestors (MRO)**

This view inherits methods and attributes from the following views:

- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.base.ContextMixin`
- `django.views.generic.base.View`

**Method Flowchart**

1. `dispatch()`
2. `http_method_not_allowed()`
3. `get_context_data()`

**Example views.py:**

```
from django.views.generic.base import TemplateView

from articles.models import Article

class HomePageView(TemplateView):

    template_name = "home.html"

    def get_context_data(self, **kwargs):
        context = super(HomePageView, self).get_context_data(**kwargs)
        context['latest_articles'] = Article.objects.all()[:5]
        return context
```

#### Example urls.py:

```
from django.conf.urls import url

from myapp.views import HomePageView

urlpatterns = [
    url(r'^$', HomePageView.as_view(), name='home'),
]
```

#### Context

- Populated (through *ContextMixin*) with the keyword arguments captured from the URL pattern that served the view.

#### RedirectView

**class** `django.views.generic.base.RedirectView`

Redirects to a given URL.

The given URL may contain dictionary-style string formatting, which will be interpolated against the parameters captured in the URL. Because keyword interpolation is *always* done (even if no arguments are passed in), any "%" characters in the URL must be written as "%" so that Python will convert them to a single percent sign on output.

If the given URL is None, Django will return an `HttpResponseGone` (410).

#### Ancestors (MRO)

This view inherits methods and attributes from the following view:

- `django.views.generic.base.View`

#### Method Flowchart

1. `dispatch()`
2. `http_method_not_allowed()`
3. `get_redirect_url()`

#### Example views.py:

```
from django.shortcuts import get_object_or_404
from django.views.generic.base import RedirectView

from articles.models import Article
```

```
class ArticleCounterRedirectView(RedirectView):

    permanent = False
    query_string = True
    pattern_name = 'article-detail'

    def get_redirect_url(self, *args, **kwargs):
        article = get_object_or_404(Article, pk=kwargs['pk'])
        article.update_counter()
        return super(ArticleCounterRedirectView, self).get_redirect_url(*args,
↪**kwargs)
```

**Example urls.py:**

```
from django.conf.urls import url
from django.views.generic.base import RedirectView

from article.views import ArticleCounterRedirectView, ArticleDetail

urlpatterns = [
    url(r'^counter/(?P<pk>[0-9]+)/$', ArticleCounterRedirectView.as_view(), name=
↪'article-counter'),
    url(r'^details/(?P<pk>[0-9]+)/$', ArticleDetail.as_view(), name='article-
↪detail'),
    url(r'^go-to-django/$', RedirectView.as_view(url='https://djangoproject.com'),
↪ name='go-to-django'),
]
```

**Attributes****url**

The URL to redirect to, as a string. Or None to raise a 410 (Gone) HTTP error.

**pattern\_name**

The name of the URL pattern to redirect to. Reversing will be done using the same args and kwargs as are passed in for this view.

**permanent**

Whether the redirect should be permanent. The only difference here is the HTTP status code returned. If True, then the redirect will use status code 301. If False, then the redirect will use status code 302. By default, permanent is False.

The default value of the permanent attribute changed from True to False.

**query\_string**

Whether to pass along the GET query string to the new location. If True, then the query string is appended to the URL. If False, then the query string is discarded. By default, query\_string is False.

**Methods****get\_redirect\_url(\*args, \*\*kwargs)**

Constructs the target URL for redirection.

The default implementation uses `url` as a starting string and performs expansion of `%` named parameters in that string using the named groups captured in the URL.

If `url` is not set, `get_redirect_url()` tries to reverse the `pattern_name` using what was captured in the URL (both named and unnamed groups are used).

If requested by *query\_string*, it will also append the query string to the generated URL. Subclasses may implement any behavior they wish, as long as the method returns a redirect-ready URL string.

## 6.3.2 Generic display views

The two following generic class-based views are designed to display data. On many projects they are typically the most commonly used views.

### DetailView

**class** `django.views.generic.detail.DetailView`

While this view is executing, `self.object` will contain the object that the view is operating upon.

#### Ancestors (MRO)

This view inherits methods and attributes from the following views:

- `django.views.generic.detail.SingleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.detail.BaseDetailView`
- `django.views.generic.detail.SingleObjectMixin`
- `django.views.generic.base.View`

#### Method Flowchart

1. `dispatch()`
2. `http_method_not_allowed()`
3. `get_template_names()`
4. `get_slug_field()`
5. `get_queryset()`
6. `get_object()`
7. `get_context_object_name()`
8. `get_context_data()`
9. `get()`
10. `render_to_response()`

#### Example `myapp/views.py`:

```
from django.views.generic.detail import DetailView
from django.utils import timezone

from articles.models import Article

class ArticleDetailView(DetailView):

    model = Article

    def get_context_data(self, **kwargs):
        context = super(ArticleDetailView, self).get_context_data(**kwargs)
```

```
context['now'] = timezone.now()
return context
```

**Example myapp/urls.py:**

```
from django.conf.urls import url

from article.views import ArticleDetailView

urlpatterns = [
    url(r'^(?P<slug>[-\w]+)/$', ArticleDetailView.as_view(), name='article-detail
↵'),
]
```

**Example myapp/article\_detail.html:**

```
<h1>{{ object.headline }}</h1>
<p>{{ object.content }}</p>
<p>Reporter: {{ object.reporter }}</p>
<p>Published: {{ object.pub_date|date }}</p>
<p>Date: {{ now|date }}</p>
```

**ListView**

**class** `django.views.generic.list.ListView`

A page representing a list of objects.

While this view is executing, `self.object_list` will contain the list of objects (usually, but not necessarily a queryset) that the view is operating upon.

**Ancestors (MRO)**

This view inherits methods and attributes from the following views:

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.list.BaseListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.base.View`

**Method Flowchart**

1. `dispatch()`
2. `http_method_not_allowed()`
3. `get_template_names()`
4. `get_queryset()`
5. `get_context_object_name()`
6. `get_context_data()`
7. `get()`
8. `render_to_response()`

**Example views.py:**

```
from django.views.generic.list import ListView
from django.utils import timezone

from articles.models import Article

class ArticleListView(ListView):

    model = Article

    def get_context_data(self, **kwargs):
        context = super(ArticleListView, self).get_context_data(**kwargs)
        context['now'] = timezone.now()
        return context
```

**Example myapp/urls.py:**

```
from django.conf.urls import url

from article.views import ArticleListView

urlpatterns = [
    url(r'^$', ArticleListView.as_view(), name='article-list'),
]
```

**Example myapp/article\_list.html:**

```
<h1>Articles</h1>
<ul>
  {% for article in object_list %}
    <li>{{ article.pub_date|date }} - {{ article.headline }}</li>
  {% empty %}
    <li>No articles yet.</li>
  {% endfor %}
</ul>
```

**class** `django.views.generic.list.BaseListView`

A base view for displaying a list of objects. It is not intended to be used directly, but rather as a parent class of the `django.views.generic.list.ListView` or other views representing lists of objects.

**Ancestors (MRO)**

This view inherits methods and attributes from the following views:

- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.base.View`

**Methods**

**get** (*request*, \**args*, \*\**kwargs*)

Adds `object_list` to the context. If `allow_empty` is True then display an empty list. If `allow_empty` is False then raise a 404 error.

### 6.3.3 Generic editing views

The following views are described on this page and provide a foundation for editing content:

- `django.views.generic.edit.FormView`

- `django.views.generic.edit.CreateView`
- `django.views.generic.edit.UpdateView`
- `django.views.generic.edit.DeleteView`

**Note:** Some of the examples on this page assume that an `Author` model has been defined as follows in `myapp/models.py`:

```
from django.urls import reverse
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=200)

    def get_absolute_url(self):
        return reverse('author-detail', kwargs={'pk': self.pk})
```

## FormView

**class** `django.views.generic.edit.FormView`

A view that displays a form. On error, redisplay the form with validation errors; on success, redirects to a new URL.

### Ancestors (MRO)

This view inherits methods and attributes from the following views:

- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.edit.BaseFormView`
- `django.views.generic.edit.FormMixin`
- `django.views.generic.edit.ProcessFormView`
- `django.views.generic.base.View`

**Example** `myapp/forms.py`:

```
from django import forms

class ContactForm(forms.Form):
    name = forms.CharField()
    message = forms.CharField(widget=forms.Textarea)

    def send_email(self):
        # send email using the self.cleaned_data dictionary
        pass
```

**Example** `myapp/views.py`:

```
from myapp.forms import ContactForm
from django.views.generic.edit import FormView

class ContactView(FormView):
    template_name = 'contact.html'
    form_class = ContactForm
    success_url = '/thanks/'
```

```
def form_valid(self, form):
    # This method is called when valid form data has been POSTed.
    # It should return an HttpResponseRedirect.
    form.send_email()
    return super(ContactView, self).form_valid(form)
```

**Example myapp/contact.html:**

```
<form action="" method="post">{% csrf_token %}
  {{ form.as_p }}
  <input type="submit" value="Send message" />
</form>
```

**CreateView**

**class** `django.views.generic.edit.CreateView`

A view that displays a form for creating an object, redisplaying the form with validation errors (if there are any) and saving the object.

**Ancestors (MRO)**

This view inherits methods and attributes from the following views:

- `django.views.generic.detail.SingleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.edit.BaseCreateView`
- `django.views.generic.edit.ModelFormMixin`
- `django.views.generic.edit.FormMixin`
- `django.views.generic.detail.SingleObjectMixin`
- `django.views.generic.edit.ProcessFormView`
- `django.views.generic.base.View`

**Attributes****template\_name\_suffix**

The `CreateView` page displayed to a GET request uses a `template_name_suffix` of `'_form'`. For example, changing this attribute to `'_create_form'` for a view creating objects for the example `Author` model would cause the default `template_name` to be `'myapp/author_create_form.html'`.

**object**

When using `CreateView` you have access to `self.object`, which is the object being created. If the object hasn't been created yet, the value will be `None`.

**Example myapp/views.py:**

```
from django.views.generic.edit import CreateView
from myapp.models import Author

class AuthorCreate(CreateView):
    model = Author
    fields = ['name']
```

**Example myapp/author\_form.html:**

```
<form action="" method="post">{% csrf_token %}
  {{ form.as_p }}
  <input type="submit" value="Save" />
</form>
```

**UpdateView****class** `django.views.generic.edit.UpdateView`

A view that displays a form for editing an existing object, redisplaying the form with validation errors (if there are any) and saving changes to the object. This uses a form automatically generated from the object's model class (unless a form class is manually specified).

**Ancestors (MRO)**

This view inherits methods and attributes from the following views:

- `django.views.generic.detail.SingleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.edit.BaseUpdateView`
- `django.views.generic.edit.ModelFormMixin`
- `django.views.generic.edit.FormMixin`
- `django.views.generic.detail.SingleObjectMixin`
- `django.views.generic.edit.ProcessFormView`
- `django.views.generic.base.View`

**Attributes****template\_name\_suffix**

The UpdateView page displayed to a GET request uses a `template_name_suffix` of `'_form'`. For example, changing this attribute to `'_update_form'` for a view updating objects for the example Author model would cause the default `template_name` to be `'myapp/author_update_form.html'`.

**object**

When using UpdateView you have access to `self.object`, which is the object being updated.

**Example myapp/views.py:**

```
from django.views.generic.edit import UpdateView
from myapp.models import Author

class AuthorUpdate(UpdateView):
    model = Author
    fields = ['name']
    template_name_suffix = '_update_form'
```

**Example myapp/author\_update\_form.html:**

```
<form action="" method="post">{% csrf_token %}
  {{ form.as_p }}
  <input type="submit" value="Update" />
</form>
```

## DeleteView

### class `django.views.generic.edit.DeleteView`

A view that displays a confirmation page and deletes an existing object. The given object will only be deleted if the request method is `POST`. If this view is fetched via `GET`, it will display a confirmation page that should contain a form that `POSTs` to the same URL.

#### Ancestors (MRO)

This view inherits methods and attributes from the following views:

- `django.views.generic.detail.SingleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.edit.BaseDeleteView`
- `django.views.generic.edit.DeletionMixin`
- `django.views.generic.detail.BaseDetailView`
- `django.views.generic.detail.SingleObjectMixin`
- `django.views.generic.base.View`

#### Attributes

##### `template_name_suffix`

The `DeleteView` page displayed to a `GET` request uses a `template_name_suffix` of `'_confirm_delete'`. For example, changing this attribute to `'_check_delete'` for a view deleting objects for the example `Author` model would cause the default `template_name` to be `'myapp/author_check_delete.html'`.

#### Example `myapp/views.py`:

```
from django.views.generic.edit import DeleteView
from django.urls import reverse_lazy
from myapp.models import Author

class AuthorDelete(DeleteView):
    model = Author
    success_url = reverse_lazy('author-list')
```

#### Example `myapp/author_confirm_delete.html`:

```
<form action="" method="post">{% csrf_token %}
  <p>Are you sure you want to delete "{{ object }}"?</p>
  <input type="submit" value="Confirm" />
</form>
```

## 6.3.4 Generic date views

Date-based generic views, provided in `django.views.generic.dates`, are views for displaying drilldown pages for date-based data.

---

**Note:** Some of the examples on this page assume that an `Article` model has been defined as follows in `myapp/models.py`:

```

from django.db import models
from django.urls import reverse

class Article(models.Model):
    title = models.CharField(max_length=200)
    pub_date = models.DateField()

    def get_absolute_url(self):
        return reverse('article-detail', kwargs={'pk': self.pk})

```

## ArchiveIndexView

### class ArchiveIndexView

A top-level index page showing the “latest” objects, by date. Objects with a date in the *future* are not included unless you set `allow_future` to `True`.

#### Ancestors (MRO)

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseArchiveIndexView`
- `django.views.generic.dates.BaseDateListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

#### Context

In addition to the context provided by `django.views.generic.list.MultipleObjectMixin` (via `django.views.generic.dates.BaseDateListView`), the template’s context will be:

- `date_list`: A `QuerySet` object containing all years that have objects available according to `queryset`, represented as `datetime.datetime` objects, in descending order.

#### Notes

- Uses a default `context_object_name` of `latest`.
- Uses a default `template_name_suffix` of `_archive`.
- Defaults to providing `date_list` by year, but this can be altered to month or day using the attribute `date_list_period`. This also applies to all subclass views.

#### Example `myapp/urls.py`:

```

from django.conf.urls import url
from django.views.generic.dates import ArchiveIndexView

from myapp.models import Article

urlpatterns = [
    url(r'^archive/$',
        ArchiveIndexView.as_view(model=Article, date_field="pub_date"),
        name="article_archive"),
]

```

**Example myapp/article\_archive.html:**

```
<ul>
  {% for article in latest %}
    <li>{{ article.pub_date }}: {{ article.title }}</li>
  {% endfor %}
</ul>
```

This will output all articles.

**YearArchiveView****class YearArchiveView**

A yearly archive page showing all available months in a given year. Objects with a date in the *future* are not displayed unless you set `allow_future` to `True`.

**Ancestors (MRO)**

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseYearArchiveView`
- `django.views.generic.dates.YearMixin`
- `django.views.generic.dates.BaseDateListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

**make\_object\_list**

A boolean specifying whether to retrieve the full list of objects for this year and pass those to the template. If `True`, the list of objects will be made available to the context. If `False`, the `None` queryset will be used as the object list. By default, this is `False`.

**get\_make\_object\_list()**

Determine if an object list will be returned as part of the context. Returns `make_object_list` by default.

**Context**

In addition to the context provided by `django.views.generic.list.MultipleObjectMixin` (via `django.views.generic.dates.BaseDateListView`), the template's context will be:

- `date_list`: A `QuerySet` object containing all months that have objects available according to queryset, represented as `datetime.datetime` objects, in ascending order.
- `year`: A `date` object representing the given year.
- `next_year`: A `date` object representing the first day of the next year, according to `allow_empty` and `allow_future`.
- `previous_year`: A `date` object representing the first day of the previous year, according to `allow_empty` and `allow_future`.

**Notes**

- Uses a default `template_name_suffix` of `_archive_year`.

**Example myapp/views.py:**

```

from django.views.generic.dates import YearArchiveView

from myapp.models import Article

class ArticleYearArchiveView(YearArchiveView):
    queryset = Article.objects.all()
    date_field = "pub_date"
    make_object_list = True
    allow_future = True

```

**Example myapp/urls.py:**

```

from django.conf.urls import url

from myapp.views import ArticleYearArchiveView

urlpatterns = [
    url(r'^(?P<year>[0-9]{4})/$',
        ArticleYearArchiveView.as_view(),
        name="article_year_archive"),
]

```

**Example myapp/article\_archive\_year.html:**

```

<ul>
  {% for date in date_list %}
    <li>{{ date|date }}</li>
  {% endfor %}
</ul>

<div>
  <h1>All Articles for {{ year|date:"Y" }}</h1>
  {% for obj in object_list %}
    <p>
      {{ obj.title }} - {{ obj.pub_date|date:"F j, Y" }}
    </p>
  {% endfor %}
</div>

```

**MonthArchiveView****class MonthArchiveView**

A monthly archive page showing all objects in a given month. Objects with a date in the *future* are not displayed unless you set `allow_future` to `True`.

**Ancestors (MRO)**

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseMonthArchiveView`
- `django.views.generic.dates.YearMixin`
- `django.views.generic.dates.MonthMixin`
- `django.views.generic.dates.BaseDateListView`

- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

### Context

In addition to the context provided by `MultipleObjectMixin` (via `BaseDateListView`), the template's context will be:

- `date_list`: A `QuerySet` object containing all days that have objects available in the given month, according to `queryset`, represented as `datetime.datetime` objects, in ascending order.
- `month`: A `date` object representing the given month.
- `next_month`: A `date` object representing the first day of the next month, according to `allow_empty` and `allow_future`.
- `previous_month`: A `date` object representing the first day of the previous month, according to `allow_empty` and `allow_future`.

### Notes

- Uses a default `template_name_suffix` of `_archive_month`.

### Example `myapp/views.py`:

```
from django.views.generic.dates import MonthArchiveView

from myapp.models import Article

class ArticleMonthArchiveView(MonthArchiveView):
    queryset = Article.objects.all()
    date_field = "pub_date"
    allow_future = True
```

### Example `myapp/urls.py`:

```
from django.conf.urls import url

from myapp.views import ArticleMonthArchiveView

urlpatterns = [
    # Example: /2012/aug/
    url(r'^(?P<year>[0-9]{4})/(?P<month>[-\w]+)/$',
        ArticleMonthArchiveView.as_view(),
        name="archive_month"),
    # Example: /2012/08/
    url(r'^(?P<year>[0-9]{4})/(?P<month>[0-9]+)/$',
        ArticleMonthArchiveView.as_view(month_format='%m'),
        name="archive_month_numeric"),
]
```

### Example `myapp/article_archive_month.html`:

```
<ul>
  {% for article in object_list %}
    <li>{{ article.pub_date|date:"F j, Y" }}: {{ article.title }}</li>
  {% endfor %}
</ul>
```

```
<p>
  {% if previous_month %}
    Previous Month: {{ previous_month|date:"F Y" }}
  {% endif %}
  {% if next_month %}
    Next Month: {{ next_month|date:"F Y" }}
  {% endif %}
</p>
```

## WeekArchiveView

### class WeekArchiveView

A weekly archive page showing all objects in a given week. Objects with a date in the *future* are not displayed unless you set `allow_future` to `True`.

#### Ancestors (MRO)

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseWeekArchiveView`
- `django.views.generic.dates.YearMixin`
- `django.views.generic.dates.WeekMixin`
- `django.views.generic.dates.BaseDateListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

#### Context

In addition to the context provided by `MultipleObjectMixin` (via `BaseDateListView`), the template's context will be:

- `week`: A `date` object representing the first day of the given week.
- `next_week`: A `date` object representing the first day of the next week, according to `allow_empty` and `allow_future`.
- `previous_week`: A `date` object representing the first day of the previous week, according to `allow_empty` and `allow_future`.

#### Notes

- Uses a default `template_name_suffix` of `_archive_week`.
- The `week_format` attribute is a `strptime()` format string used to parse the week number. The following values are supported:
  - `'%U'`: Based on the United States week system where the week begins on Sunday. This is the default value.
  - `'%W'`: Similar to `'%U'`, except it assumes that the week begins on Monday. This is not the same as the ISO 8601 week number.

#### Example myapp/views.py:

```
from django.views.generic.dates import WeekArchiveView

from myapp.models import Article

class ArticleWeekArchiveView(WeekArchiveView):
    queryset = Article.objects.all()
    date_field = "pub_date"
    week_format = "%W"
    allow_future = True
```

#### Example myapp/urls.py:

```
from django.conf.urls import url

from myapp.views import ArticleWeekArchiveView

urlpatterns = [
    # Example: /2012/week/23/
    url(r'^(?P<year>[0-9]{4})/week/(?P<week>[0-9]+)/$',
        ArticleWeekArchiveView.as_view(),
        name="archive_week"),
]
```

#### Example myapp/article\_archive\_week.html:

```
<h1>Week {{ week|date:'W' }}</h1>

<ul>
    {% for article in object_list %}
        <li>{{ article.pub_date|date:"F j, Y" }}: {{ article.title }}</li>
    {% endfor %}
</ul>

<p>
    {% if previous_week %}
        Previous Week: {{ previous_week|date:"W" }} of year {{ previous_week|date:
    ↪"Y" }}
    {% endif %}
    {% if previous_week and next_week %}--{% endif %}
    {% if next_week %}
        Next week: {{ next_week|date:"W" }} of year {{ next_week|date:"Y" }}
    {% endif %}
</p>
```

In this example, you are outputting the week number. Keep in mind that week numbers computed by the `date` template filter with the `'W'` format character are not always the same as those computed by `strftime()` and `strptime()` with the `'%W'` format string. For year 2015, for example, week numbers output by `date` are higher by one compared to those output by `strftime()`. There isn't an equivalent for the `'%U'` `strftime()` format string in `date`. Therefore, you should avoid using `date` to generate URLs for `WeekArchiveView`.

### DayArchiveView

#### class DayArchiveView

A day archive page showing all objects in a given day. Days in the future throw a 404 error, regardless of whether any objects exist for future days, unless you set `allow_future` to `True`.

### Ancestors (MRO)

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseDayArchiveView`
- `django.views.generic.dates.YearMixin`
- `django.views.generic.dates.MonthMixin`
- `django.views.generic.dates.DayMixin`
- `django.views.generic.dates.BaseDateListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

### Context

In addition to the context provided by `MultipleObjectMixin` (via `BaseDateListView`), the template's context will be:

- `day`: A `date` object representing the given day.
- `next_day`: A `date` object representing the next day, according to `allow_empty` and `allow_future`.
- `previous_day`: A `date` object representing the previous day, according to `allow_empty` and `allow_future`.
- `next_month`: A `date` object representing the first day of the next month, according to `allow_empty` and `allow_future`.
- `previous_month`: A `date` object representing the first day of the previous month, according to `allow_empty` and `allow_future`.

### Notes

- Uses a default `template_name_suffix` of `_archive_day`.

### Example myapp/views.py:

```
from django.views.generic.dates import DayArchiveView

from myapp.models import Article

class ArticleDayArchiveView(DayArchiveView):
    queryset = Article.objects.all()
    date_field = "pub_date"
    allow_future = True
```

### Example myapp/urls.py:

```
from django.conf.urls import url

from myapp.views import ArticleDayArchiveView

urlpatterns = [
    # Example: /2012/nov/10/
    url(r'^(?P<year>[0-9]{4})/(?P<month>[-\w]+)/(?P<day>[0-9]+)/$',
```

```
ArticleDayArchiveView.as_view(),
name="archive_day"),
]
```

Example `myapp/article_archive_day.html`:

```
<h1>{{ day }}</h1>

<ul>
  {% for article in object_list %}
    <li>{{ article.pub_date|date:"F j, Y" }}: {{ article.title }}</li>
  {% endfor %}
</ul>

<p>
  {% if previous_day %}
    Previous Day: {{ previous_day }}
  {% endif %}
  {% if previous_day and next_day %}--{% endif %}
  {% if next_day %}
    Next Day: {{ next_day }}
  {% endif %}
</p>
```

## TodayArchiveView

### class `TodayArchiveView`

A day archive page showing all objects for *today*. This is exactly the same as `django.views.generic.dates.DayArchiveView`, except today's date is used instead of the year/month/day arguments.

### Ancestors (MRO)

- `django.views.generic.list.MultipleObjectTemplateResponseMixin`
- `django.views.generic.base.TemplateResponseMixin`
- `django.views.generic.dates.BaseTodayArchiveView`
- `django.views.generic.dates.BaseDayArchiveView`
- `django.views.generic.dates.YearMixin`
- `django.views.generic.dates.MonthMixin`
- `django.views.generic.dates.DayMixin`
- `django.views.generic.dates.BaseDateListView`
- `django.views.generic.list.MultipleObjectMixin`
- `django.views.generic.dates.DateMixin`
- `django.views.generic.base.View`

### Notes

- Uses a default `template_name_suffix` of `_archive_today`.

Example `myapp/views.py`:

```
from django.views.generic.dates import TodayArchiveView

from myapp.models import Article

class ArticleTodayArchiveView(TodayArchiveView):
    queryset = Article.objects.all()
    date_field = "pub_date"
    allow_future = True
```

**Example myapp/urls.py:**

```
from django.conf.urls import url

from myapp.views import ArticleTodayArchiveView

urlpatterns = [
    url(r'^today/$',
        ArticleTodayArchiveView.as_view(),
        name="archive_today"),
]
```

---

**Where is the example template for TodayArchiveView?**

This view uses by default the same template as the *DayArchiveView*, which is in the previous example. If you need a different template, set the `template_name` attribute to be the name of the new template.

---

**DateDetailView****class DateDetailView**

A page representing an individual object. If the object has a date value in the future, the view will throw a 404 error by default, unless you set `allow_future` to `True`.

**Ancestors (MRO)**

- *django.views.generic.detail.SingleObjectTemplateResponseMixin*
- *django.views.generic.base.TemplateResponseMixin*
- *django.views.generic.dates.BaseDateDetailView*
- *django.views.generic.dates.YearMixin*
- *django.views.generic.dates.MonthMixin*
- *django.views.generic.dates.DayMixin*
- *django.views.generic.dates.DateMixin*
- *django.views.generic.detail.BaseDetailView*
- *django.views.generic.detail.SingleObjectMixin*
- *django.views.generic.base.View*

**Context**

- Includes the single object associated with the `model` specified in the `DateDetailView`.

**Notes**

- Uses a default `template_name_suffix` of `_detail`.

Example `myapp/urls.py`:

```
from django.conf.urls import url
from django.views.generic.dates import DateDetailView

urlpatterns = [
    url(r'^(?P<year>[0-9]{4})/(?P<month>[-\w]+)/(?P<day>[0-9]+)/(?P<pk>[0-9]+)/$',
        DateDetailView.as_view(model=Article, date_field="pub_date"),
        name="archive_date_detail"),
]
```

Example `myapp/article_detail.html`:

```
<h1>{{ object.title }}</h1>
```

---

**Note:** All of the generic views listed above have matching Base views that only differ in that they do not include the *MultipleObjectTemplateResponseMixin* (for the archive views) or *SingleObjectTemplateResponseMixin* (for the *DateDetailView*):

```
class BaseArchiveIndexView
```

```
class BaseYearArchiveView
```

```
class BaseMonthArchiveView
```

```
class BaseWeekArchiveView
```

```
class BaseDayArchiveView
```

```
class BaseTodayArchiveView
```

```
class BaseDateDetailView
```

---

## 6.3.5 Class-based views mixins

Class-based views API reference. For introductory material, see *Using mixins with class-based views*.

### Simple mixins

#### ContextMixin

```
class django.views.generic.base.ContextMixin
```

##### Methods

```
get_context_data (**kwargs)
```

Returns a dictionary representing the template context. The keyword arguments provided will make up the returned context. Example usage:

```
def get_context_data(self, **kwargs):
    context = super(RandomNumberView, self).get_context_data(**kwargs)
    context['number'] = random.randrange(1, 100)
    return context
```

The template context of all class-based generic views include a `view` variable that points to the `View` instance.

---

#### Use `alters_data` where appropriate

Note that having the view instance in the template context may expose potentially hazardous methods to template authors. To prevent methods like this from being called in the template, set `alters_data=True` on those methods. For more information, read the documentation on [rendering a template context](#).

---

### TemplateResponseMixin

**class** `django.views.generic.base.TemplateResponseMixin`

Provides a mechanism to construct a `TemplateResponse`, given suitable context. The template to use is configurable and can be further customized by subclasses.

#### Attributes

##### `template_name`

The full name of a template to use as defined by a string. Not defining a `template_name` will raise a `django.core.exceptions.ImproperlyConfigured` exception.

##### `template_engine`

The *NAME* of a template engine to use for loading the template. `template_engine` is passed as the using keyword argument to `response_class`. Default is `None`, which tells Django to search for the template in all configured engines.

##### `response_class`

The response class to be returned by `render_to_response` method. Default is `TemplateResponse`. The template and context of `TemplateResponse` instances can be altered later (e.g. in [template response middleware](#)).

If you need custom template loading or custom context object instantiation, create a `TemplateResponse` subclass and assign it to `response_class`.

##### `content_type`

The content type to use for the response. `content_type` is passed as a keyword argument to `response_class`. Default is `None` – meaning that Django uses `DEFAULT_CONTENT_TYPE`.

#### Methods

**`render_to_response`** (*context*, *\*\*response\_kwargs*)

Returns a `self.response_class` instance.

If any keyword arguments are provided, they will be passed to the constructor of the response class.

Calls `get_template_names()` to obtain the list of template names that will be searched looking for an existent template.

**`get_template_names`** ()

Returns a list of template names to search for when rendering the template. The first template that is found will be used.

If `template_name` is specified, the default implementation will return a list containing `template_name` (if it is specified).

## Single object mixins

### SingleObjectMixin

**class** `django.views.generic.detail.SingleObjectMixin`

Provides a mechanism for looking up an object associated with the current HTTP request.

#### Methods and Attributes

##### `model`

The model that this view will display data for. Specifying `model = Foo` is effectively the same as specifying `queryset = Foo.objects.all()`, where `objects` stands for `Foo`'s *default manager*.

##### `queryset`

A `QuerySet` that represents the objects. If provided, the value of `queryset` supersedes the value provided for `model`.

**Warning:** `queryset` is a class attribute with a *mutable* value so care must be taken when using it directly. Before using it, either call its `all()` method or retrieve it with `get_queryset()` which takes care of the cloning behind the scenes.

##### `slug_field`

The name of the field on the model that contains the slug. By default, `slug_field` is `'slug'`.

##### `slug_url_kwarg`

The name of the URLConf keyword argument that contains the slug. By default, `slug_url_kwarg` is `'slug'`.

##### `pk_url_kwarg`

The name of the URLConf keyword argument that contains the primary key. By default, `pk_url_kwarg` is `'pk'`.

##### `context_object_name`

Designates the name of the variable to use in the context.

##### `query_pk_and_slug`

If `True`, causes `get_object()` to perform its lookup using both the primary key and the slug. Defaults to `False`.

This attribute can help mitigate [insecure direct object reference](#) attacks. When applications allow access to individual objects by a sequential primary key, an attacker could brute-force guess all URLs; thereby obtaining a list of all objects in the application. If users with access to individual objects should be prevented from obtaining this list, setting `query_pk_and_slug` to `True` will help prevent the guessing of URLs as each URL will require two correct, non-sequential arguments. Simply using a unique slug may serve the same purpose, but this scheme allows you to have non-unique slugs.

##### `get_object (queryset=None)`

Returns the single object that this view will display. If `queryset` is provided, that `queryset` will be used as the source of objects; otherwise, `get_queryset()` will be used. `get_object()` looks for a `pk_url_kwarg` argument in the arguments to the view; if this argument is found, this method performs a primary-key based lookup using that value. If this argument is not found, it looks for a `slug_url_kwarg` argument, and performs a slug lookup using the `slug_field`.

When `query_pk_and_slug` is `True`, `get_object()` will perform its lookup using both the primary key and the slug.

##### `get_queryset ()`

Returns the `queryset` that will be used to retrieve the object that this view will display. By default,

`get_queryset()` returns the value of the `queryset` attribute if it is set, otherwise it constructs a `QuerySet` by calling the `all()` method on the `model` attribute's default manager.

**`get_context_object_name(obj)`**

Return the context variable name that will be used to contain the data that this view is manipulating. If `context_object_name` is not set, the context name will be constructed from the `model_name` of the model that the queryset is composed from. For example, the model `Article` would have context object named `'article'`.

**`get_context_data(**kwargs)`**

Returns context data for displaying the list of objects.

The base implementation of this method requires that the `self.object` attribute be set by the view (even if `None`). Be sure to do this if you are using this mixin without one of the built-in views that does so.

It returns a dictionary with these contents:

- `object`: The object that this view is displaying (`self.object`).
- `context_object_name`: `self.object` will also be stored under the name returned by `get_context_object_name()`, which defaults to the lowercased version of the model name.

---

#### Context variables override values from template context processors

Any variables from `get_context_data()` take precedence over context variables from `context processors`. For example, if your view sets the `model` attribute to `User`, the default context object name of `user` would override the `user` variable from the `django.contrib.auth.context_processors.auth()` context processor. Use `get_context_object_name()` to avoid a clash.

---

**`get_slug_field()`**

Returns the name of a slug field to be used to look up by slug. By default this simply returns the value of `slug_field`.

### SingleObjectTemplateResponseMixin

**`class django.views.generic.detail.SingleObjectTemplateResponseMixin`**

A mixin class that performs template-based response rendering for views that operate upon a single object instance. Requires that the view it is mixed with provides `self.object`, the object instance that the view is operating on. `self.object` will usually be, but is not required to be, an instance of a Django model. It may be `None` if the view is in the process of constructing a new instance.

#### Extends

- `TemplateResponseMixin`

#### Methods and Attributes

**`template_name_field`**

The field on the current object instance that can be used to determine the name of a candidate template. If either `template_name_field` itself or the value of the `template_name_field` on the current object instance is `None`, the object will not be used for a candidate template name.

**`template_name_suffix`**

The suffix to append to the auto-generated candidate template name. Default suffix is `_detail`.

**get\_template\_names()**

Returns a list of candidate template names. Returns the following list:

- the value of `template_name` on the view (if provided)
- the contents of the `template_name_field` field on the object instance that the view is operating upon (if available)
- `<app_label>/<model_name><template_name_suffix>.html`

## Multiple object mixins

### MultipleObjectMixin

**class** `django.views.generic.list.MultipleObjectMixin`

A mixin that can be used to display a list of objects.

If `paginate_by` is specified, Django will paginate the results returned by this. You can specify the page number in the URL in one of two ways:

- Use the `page` parameter in the URLconf. For example, this is what your URLconf might look like:

```
url(r'^objects/page(?:P<page>[0-9]+)/$', PaginatedView.as_view()),
```

- Pass the page number via the `page` query-string parameter. For example, a URL would look like this:

```
/objects/?page=3
```

These values and lists are 1-based, not 0-based, so the first page would be represented as page 1.

For more on pagination, read the [pagination documentation](#).

As a special case, you are also permitted to use `last` as a value for `page`:

```
/objects/?page=last
```

This allows you to access the final page of results without first having to determine how many pages there are.

Note that `page` *must* be either a valid page number or the value `last`; any other value for `page` will result in a 404 error.

### Extends

- `django.views.generic.base.ContextMixin`

### Methods and Attributes

#### **allow\_empty**

A boolean specifying whether to display the page if no objects are available. If this is `False` and no objects are available, the view will raise a 404 instead of displaying an empty page. By default, this is `True`.

#### **model**

The model that this view will display data for. Specifying `model = Foo` is effectively the same as specifying `queryset = Foo.objects.all()`, where `objects` stands for `Foo`'s *default manager*.

#### **queryset**

A `QuerySet` that represents the objects. If provided, the value of `queryset` supersedes the value provided for `model`.

**Warning:** `queryset` is a class attribute with a *mutable* value so care must be taken when using it directly. Before using it, either call its `all()` method or retrieve it with `get_queryset()` which takes care of the cloning behind the scenes.

**ordering**

A string or list of strings specifying the ordering to apply to the `queryset`. Valid values are the same as those for `order_by()`.

**paginate\_by**

An integer specifying how many objects should be displayed per page. If this is given, the view will paginate objects with `paginate_by` objects per page. The view will expect either a `page` query string parameter (via `request.GET`) or a `page` variable specified in the URLconf.

**paginate\_orphans**

An integer specifying the number of “overflow” objects the last page can contain. This extends the `paginate_by` limit on the last page by up to `paginate_orphans`, in order to keep the last page from having a very small number of objects.

**page\_kwarg**

A string specifying the name to use for the page parameter. The view will expect this parameter to be available either as a query string parameter (via `request.GET`) or as a kwarg variable specified in the URLconf. Defaults to `page`.

**paginator\_class**

The paginator class to be used for pagination. By default, `django.core.paginator.Paginator` is used. If the custom paginator class doesn’t have the same constructor interface as `django.core.paginator.Paginator`, you will also need to provide an implementation for `get_paginator()`.

**context\_object\_name**

Designates the name of the variable to use in the context.

**get\_queryset()**

Get the list of items for this view. This must be an iterable and may be a `queryset` (in which `queryset-specific` behavior will be enabled).

**get\_ordering()**

Returns a string (or iterable of strings) that defines the ordering that will be applied to the `queryset`.

Returns `ordering` by default.

**paginate\_queryset(queryset, page\_size)**

Returns a 4-tuple containing (`paginator`, `page`, `object_list`, `is_paginated`).

Constructed by paginating `queryset` into pages of size `page_size`. If the request contains a `page` argument, either as a captured URL argument or as a GET argument, `object_list` will correspond to the objects from that page.

**get\_paginate\_by(queryset)**

Returns the number of items to paginate by, or `None` for no pagination. By default this simply returns the value of `paginate_by`.

**get\_paginator(queryset, per\_page, orphans=0, allow\_empty\_first\_page=True)**

Returns an instance of the paginator to use for this view. By default, instantiates an instance of `paginator_class`.

**get\_paginate\_orphans()**

An integer specifying the number of “overflow” objects the last page can contain. By default this simply returns the value of `paginate_orphans`.

**get\_allow\_empty()**

Return a boolean specifying whether to display the page if no objects are available. If this method returns `False` and no objects are available, the view will raise a 404 instead of displaying an empty page. By default, this is `True`.

**get\_context\_object\_name(object\_list)**

Return the context variable name that will be used to contain the list of data that this view is manipulating. If `object_list` is a queryset of Django objects and `context_object_name` is not set, the context name will be the `model_name` of the model that the queryset is composed from, with postfix `'_list'` appended. For example, the model `Article` would have a context object named `article_list`.

**get\_context\_data(\*\*kwargs)**

Returns context data for displaying the list of objects.

**Context**

- `object_list`: The list of objects that this view is displaying. If `context_object_name` is specified, that variable will also be set in the context, with the same value as `object_list`.
- `is_paginated`: A boolean representing whether the results are paginated. Specifically, this is set to `False` if no page size has been specified, or if the available objects do not span multiple pages.
- `paginator`: An instance of `django.core.paginator.Paginator`. If the page is not paginated, this context variable will be `None`.
- `page_obj`: An instance of `django.core.paginator.Page`. If the page is not paginated, this context variable will be `None`.

**MultipleObjectTemplateResponseMixin****class django.views.generic.list.MultipleObjectTemplateResponseMixin**

A mixin class that performs template-based response rendering for views that operate upon a list of object instances. Requires that the view it is mixed with provides `self.object_list`, the list of object instances that the view is operating on. `self.object_list` may be, but is not required to be, a `QuerySet`.

**Extends**

- `TemplateResponseMixin`

**Methods and Attributes****template\_name\_suffix**

The suffix to append to the auto-generated candidate template name. Default suffix is `_list`.

**get\_template\_names()**

Returns a list of candidate template names. Returns the following list:

- the value of `template_name` on the view (if provided)
- `<app_label>/<model_name><template_name_suffix>.html`

**Editing mixins**

The following mixins are used to construct Django's editing views:

- `django.views.generic.edit.FormMixin`
- `django.views.generic.edit.ModelFormMixin`
- `django.views.generic.edit.ProcessFormView`

- `django.views.generic.edit.DeletionMixin`

---

**Note:** Examples of how these are combined into editing views can be found at the documentation on *Generic editing views*.

---

## FormMixin

**class** `django.views.generic.edit.FormMixin`

A mixin class that provides facilities for creating and displaying forms.

### Mixins

- `django.views.generic.base.ContextMixin`

### Methods and Attributes

#### **initial**

A dictionary containing initial data for the form.

#### **form\_class**

The form class to instantiate.

#### **success\_url**

The URL to redirect to when the form is successfully processed.

#### **prefix**

The *prefix* for the generated form.

#### **get\_initial()**

Retrieve initial data for the form. By default, returns a copy of *initial*.

#### **get\_form\_class()**

Retrieve the form class to instantiate. By default *form\_class*.

#### **get\_form(form\_class=None)**

Instantiate an instance of *form\_class* using *get\_form\_kwargs()*. If *form\_class* isn't provided *get\_form\_class()* will be used.

#### **get\_form\_kwargs()**

Build the keyword arguments required to instantiate the form.

The initial argument is set to *get\_initial()*. If the request is a POST or PUT, the request data (`request.POST` and `request.FILES`) will also be provided.

#### **get\_prefix()**

Determine the *prefix* for the generated form. Returns *prefix* by default.

#### **get\_success\_url()**

Determine the URL to redirect to when the form is successfully validated. Returns *success\_url* by default.

#### **form\_valid(form)**

Redirects to *get\_success\_url()*.

#### **form\_invalid(form)**

Renders a response, providing the invalid form as context.

#### **get\_context\_data(\*\*kwargs)**

Calls *get\_form()* and adds the result to the context data with the name 'form'.

## ModelFormMixin

**class** `django.views.generic.edit.ModelFormMixin`

A form mixin that works on ModelForms, rather than a standalone form.

Since this is a subclass of *SingleObjectMixin*, instances of this mixin have access to the *model* and *queryset* attributes, describing the type of object that the ModelForm is manipulating.

If you specify both the *fields* and *form\_class* attributes, an *ImproperlyConfigured* exception will be raised.

### Mixins

- `django.views.generic.edit.FormMixin`
- `django.views.generic.detail.SingleObjectMixin`

### Methods and Attributes

#### **model**

A model class. Can be explicitly provided, otherwise will be determined by examining `self.object` or `queryset`.

#### **fields**

A list of names of fields. This is interpreted the same way as the `Meta.fields` attribute of *ModelForm*.

This is a required attribute if you are generating the form class automatically (e.g. using `model`). Omitting this attribute will result in an *ImproperlyConfigured* exception.

#### **success\_url**

The URL to redirect to when the form is successfully processed.

`success_url` may contain dictionary string formatting, which will be interpolated against the object's field attributes. For example, you could use `success_url="/polls/{slug}/"` to redirect to a URL composed out of the `slug` field on a model.

#### **get\_form\_class()**

Retrieve the form class to instantiate. If *form\_class* is provided, that class will be used. Otherwise, a ModelForm will be instantiated using the model associated with the *queryset*, or with the *model*, depending on which attribute is provided.

#### **get\_form\_kwargs()**

Add the current instance (`self.object`) to the standard `get_form_kwargs()`.

#### **get\_success\_url()**

Determine the URL to redirect to when the form is successfully validated. Returns `django.views.generic.edit.ModelFormMixin.success_url` if it is provided; otherwise, attempts to use the `get_absolute_url()` of the object.

#### **form\_valid(form)**

Saves the form instance, sets the current object for the view, and redirects to `get_success_url()`.

#### **form\_invalid()**

Renders a response, providing the invalid form as context.

## ProcessFormView

**class** `django.views.generic.edit.ProcessFormView`

A mixin that provides basic HTTP GET and POST workflow.

**Note:** This is named ‘ProcessFormView’ and inherits directly from `django.views.generic.base.View`, but breaks if used independently, so it is more of a mixin.

---

#### Extends

- `django.views.generic.base.View`

#### Methods and Attributes

**get** (*request*, \**args*, \*\**kwargs*)

Renders a response using a context created with `get_context_data()`.

Construction of the form was moved from this method to `get_context_data()`.

**post** (*request*, \**args*, \*\**kwargs*)

Constructs a form, checks the form for validity, and handles it accordingly.

**put** (\**args*, \*\**kwargs*)

The PUT action is also handled and just passes all parameters through to `post()`.

#### DeletionMixin

**class** `django.views.generic.edit.DeletionMixin`

Enables handling of the DELETE http action.

#### Methods and Attributes

**success\_url**

The url to redirect to when the nominated object has been successfully deleted.

`success_url` may contain dictionary string formatting, which will be interpolated against the object’s field attributes. For example, you could use `success_url="/parent/{parent_id}/"` to redirect to a URL composed out of the `parent_id` field on a model.

**get\_success\_url** ()

Returns the url to redirect to when the nominated object has been successfully deleted. Returns `success_url` by default.

#### Date-based mixins

---

**Note:** All the date formatting attributes in these mixins use `strftime()` format characters. Do not try to use the format characters from the `now` template tag as they are not compatible.

---

#### YearMixin

**class** `YearMixin`

A mixin that can be used to retrieve and provide parsing information for a year component of a date.

#### Methods and Attributes

**year\_format**

The `strftime()` format to use when parsing the year. By default, this is ‘%Y’.

**year**

**Optional** The value for the year, as a string. By default, set to `None`, which means the year will be determined using other means.

**get\_year\_format()**

Returns the `strftime()` format to use when parsing the year. Returns `year_format` by default.

**get\_year()**

Returns the year for which this view will display data, as a string. Tries the following sources, in order:

- The value of the `YearMixin.year` attribute.
- The value of the `year` argument captured in the URL pattern.
- The value of the `year` GET query argument.

Raises a 404 if no valid year specification can be found.

**get\_next\_year(date)**

Returns a date object containing the first day of the year after the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**get\_previous\_year(date)**

Returns a date object containing the first day of the year before the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**MonthMixin****class MonthMixin**

A mixin that can be used to retrieve and provide parsing information for a month component of a date.

**Methods and Attributes****month\_format**

The `strftime()` format to use when parsing the month. By default, this is `'%b'`.

**month**

**Optional** The value for the month, as a string. By default, set to `None`, which means the month will be determined using other means.

**get\_month\_format()**

Returns the `strftime()` format to use when parsing the month. Returns `month_format` by default.

**get\_month()**

Returns the month for which this view will display data, as a string. Tries the following sources, in order:

- The value of the `MonthMixin.month` attribute.
- The value of the `month` argument captured in the URL pattern.
- The value of the `month` GET query argument.

Raises a 404 if no valid month specification can be found.

**get\_next\_month(date)**

Returns a date object containing the first day of the month after the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**get\_previous\_month** (*date*)

Returns a date object containing the first day of the month before the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**DayMixin****class DayMixin**

A mixin that can be used to retrieve and provide parsing information for a day component of a date.

**Methods and Attributes****day\_format**

The `strftime()` format to use when parsing the day. By default, this is `'%d'`.

**day**

**Optional** The value for the day, as a string. By default, set to `None`, which means the day will be determined using other means.

**get\_day\_format** ()

Returns the `strftime()` format to use when parsing the day. Returns `day_format` by default.

**get\_day** ()

Returns the day for which this view will display data, as a string. Tries the following sources, in order:

- The value of the `DayMixin.day` attribute.
- The value of the `day` argument captured in the URL pattern.
- The value of the `day` GET query argument.

Raises a 404 if no valid day specification can be found.

**get\_next\_day** (*date*)

Returns a date object containing the next valid day after the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**get\_previous\_day** (*date*)

Returns a date object containing the previous valid day. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**WeekMixin****class WeekMixin**

A mixin that can be used to retrieve and provide parsing information for a week component of a date.

**Methods and Attributes****week\_format**

The `strftime()` format to use when parsing the week. By default, this is `'%U'`, which means the week starts on Sunday. Set it to `'%W'` if your week starts on Monday.

**week**

**Optional** The value for the week, as a string. By default, set to `None`, which means the week will be determined using other means.

**get\_week\_format** ()

Returns the `strftime()` format to use when parsing the week. Returns `week_format` by default.

**get\_week()**

Returns the week for which this view will display data, as a string. Tries the following sources, in order:

- The value of the `WeekMixin.week` attribute.
- The value of the `week` argument captured in the URL pattern
- The value of the `week` GET query argument.

Raises a 404 if no valid week specification can be found.

**get\_next\_week(date)**

Returns a date object containing the first day of the week after the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**get\_prev\_week(date)**

Returns a date object containing the first day of the week before the date provided. This function can also return `None` or raise an `Http404` exception, depending on the values of `allow_empty` and `allow_future`.

**DateMixin****class DateMixin**

A mixin class providing common behavior for all date-based views.

**Methods and Attributes****date\_field**

The name of the `DateField` or `DateTimeField` in the `QuerySet`'s model that the date-based archive should use to determine the list of objects to display on the page.

When *time zone support* is enabled and `date_field` is a `DateTimeField`, dates are assumed to be in the current time zone. Otherwise, the queryset could include objects from the previous or the next day in the end user's time zone.

**Warning:** In this situation, if you have implemented per-user time zone selection, the same URL may show a different set of objects, depending on the end user's time zone. To avoid this, you should use a `DateField` as the `date_field` attribute.

**allow\_future**

A boolean specifying whether to include “future” objects on this page, where “future” means objects in which the field specified in `date_field` is greater than the current date/time. By default, this is `False`.

**get\_date\_field()**

Returns the name of the field that contains the date data that this view will operate on. Returns `date_field` by default.

**get\_allow\_future()**

Determine whether to include “future” objects on this page, where “future” means objects in which the field specified in `date_field` is greater than the current date/time. Returns `allow_future` by default.

**BaseDateListView****class BaseDateListView**

A base class that provides common behavior for all date-based views. There won't normally be a reason to

instantiate `BaseDateListView`; instantiate one of the subclasses instead.

While this view (and its subclasses) are executing, `self.object_list` will contain the list of objects that the view is operating upon, and `self.date_list` will contain the list of dates for which data is available.

### Mixins

- `DateMixin`
- `MultipleObjectMixin`

### Methods and Attributes

#### `allow_empty`

A boolean specifying whether to display the page if no objects are available. If this is `True` and no objects are available, the view will display an empty page instead of raising a 404.

This is identical to `django.views.generic.list.MultipleObjectMixin.allow_empty`, except for the default value, which is `False`.

#### `date_list_period`

**Optional** A string defining the aggregation period for `date_list`. It must be one of `'year'` (default), `'month'`, or `'day'`.

#### `get_dated_items()`

Returns a 3-tuple containing (`date_list`, `object_list`, `extra_context`).

`date_list` is the list of dates for which data is available. `object_list` is the list of objects. `extra_context` is a dictionary of context data that will be added to any context data provided by the `MultipleObjectMixin`.

#### `get_dated_queryset(**lookup)`

Returns a queryset, filtered using the query arguments defined by `lookup`. Enforces any restrictions on the queryset, such as `allow_empty` and `allow_future`.

#### `get_date_list_period()`

Returns the aggregation period for `date_list`. Returns `date_list_period` by default.

#### `get_date_list(queryset, date_type=None, ordering='ASC')`

Returns the list of dates of type `date_type` for which `queryset` contains entries. For example, `get_date_list(qs, 'year')` will return the list of years for which `qs` has entries. If `date_type` isn't provided, the result of `get_date_list_period()` is used. `date_type` and `ordering` are simply passed to `QuerySet.dates()`.

## 6.3.6 Class-based generic views - flattened index

This index provides an alternate organization of the reference documentation for class-based views. For each view, the effective attributes and methods from the class tree are represented under that view. For the reference documentation organized by the class which defines the behavior, see *Class-based views*.

### See also:

[Classy Class-Based Views](#) provides a nice interface to navigate the class hierarchy of the built-in class-based views.

## Simple generic views

### View

class `View`

**Attributes** (with optional accessor):

- `http_method_names`

**Methods**

- `as_view()`
- `dispatch()`
- `head()`
- `http_method_not_allowed()`

## TemplateView

**class TemplateView**

**Attributes** (with optional accessor):

- `content_type`
- `http_method_names`
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]

**Methods**

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `head()`
- `http_method_not_allowed()`
- `render_to_response()`

## RedirectView

**class RedirectView**

**Attributes** (with optional accessor):

- `http_method_names`
- `pattern_name`
- `permanent`
- `query_string`
- `url` [`get_redirect_url()`]

**Methods**

- `as_view()`

- `delete()`
- `dispatch()`
- `get()`
- `head()`
- `http_method_not_allowed()`
- `options()`
- `post()`
- `put()`

## Detail Views

### DetailView

#### class `DetailView`

**Attributes** (with optional accessor):

- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `http_method_names`
- `model`
- `pk_url_kwarg`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `slug_field` [`get_slug_field()`]
- `slug_url_kwarg`
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_field`
- `template_name_suffix`

#### Methods

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_object()`
- `head()`
- `http_method_not_allowed()`
- `render_to_response()`

## List Views

### ListView

#### class `ListView`

**Attributes** (with optional accessor):

- `allow_empty` [`get_allow_empty()`]
- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `http_method_names`
- `model`
- `ordering` [`get_ordering()`]
- `paginate_by` [`get_paginate_by()`]
- `paginate_orphans` [`get_paginate_orphans()`]
- `paginator_class`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_suffix`

#### **Methods**

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_paginator()`
- `head()`
- `http_method_not_allowed()`
- `paginate_queryset()`
- `render_to_response()`

## Editing views

### FormView

#### class `FormView`

**Attributes** (with optional accessor):

- `content_type`

- `form_class` [`get_form_class()`]
- `http_method_names`
- `initial` [`get_initial()`]
- `prefix` [`get_prefix()`]
- `response_class` [`render_to_response()`]
- `success_url` [`get_success_url()`]
- `template_engine`
- `template_name` [`get_template_names()`]

#### Methods

- `as_view()`
- `dispatch()`
- `form_invalid()`
- `form_valid()`
- `get()`
- `get_context_data()`
- `get_form()`
- `get_form_kwargs()`
- `http_method_not_allowed()`
- `post()`
- `put()`

#### CreateView

##### class `CreateView`

**Attributes** (with optional accessor):

- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `fields`
- `form_class` [`get_form_class()`]
- `http_method_names`
- `initial` [`get_initial()`]
- `model`
- `pk_url_kwarg`
- `prefix` [`get_prefix()`]
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `slug_field` [`get_slug_field()`]

- `slug_url_kwarg`
- `success_url` [`get_success_url()`]
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_field`
- `template_name_suffix`

#### Methods

- `as_view()`
- `dispatch()`
- `form_invalid()`
- `form_valid()`
- `get()`
- `get_context_data()`
- `get_form()`
- `get_form_kwargs()`
- `get_object()`
- `head()`
- `http_method_not_allowed()`
- `post()`
- `put()`
- `render_to_response()`

#### UpdateView

##### class UpdateView

Attributes (with optional accessor):

- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `fields`
- `form_class` [`get_form_class()`]
- `http_method_names`
- `initial` [`get_initial()`]
- `model`
- `pk_url_kwarg`
- `prefix` [`get_prefix()`]
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]

- `slug_field` [`get_slug_field()`]
- `slug_url_kwarg`
- `success_url` [`get_success_url()`]
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_field`
- `template_name_suffix`

### Methods

- `as_view()`
- `dispatch()`
- `form_invalid()`
- `form_valid()`
- `get()`
- `get_context_data()`
- `get_form()`
- `get_form_kwargs()`
- `get_object()`
- `head()`
- `http_method_not_allowed()`
- `post()`
- `put()`
- `render_to_response()`

### DeleteView

#### class DeleteView

Attributes (with optional accessor):

- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `http_method_names`
- `model`
- `pk_url_kwarg`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `slug_field` [`get_slug_field()`]
- `slug_url_kwarg`
- `success_url` [`get_success_url()`]

- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_field`
- `template_name_suffix`

#### Methods

- `as_view()`
- `delete()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_object()`
- `head()`
- `http_method_not_allowed()`
- `post()`
- `render_to_response()`

#### Date-based views

##### ArchiveIndexView

##### class ArchiveIndexView

Attributes (with optional accessor):

- `allow_empty` [`get_allow_empty()`]
- `allow_future` [`get_allow_future()`]
- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `date_field` [`get_date_field()`]
- `http_method_names`
- `model`
- `ordering` [`get_ordering()`]
- `paginate_by` [`get_paginate_by()`]
- `paginate_orphans` [`get_paginate_orphans()`]
- `paginator_class`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]

- `template_name_suffix`

#### Methods

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_date_list()`
- `get_dated_items()`
- `get_dated_queryset()`
- `get_paginator()`
- `head()`
- `http_method_not_allowed()`
- `paginate_queryset()`
- `render_to_response()`

#### YearArchiveView

##### class `YearArchiveView`

##### Attributes (with optional accessor):

- `allow_empty` [`get_allow_empty()`]
- `allow_future` [`get_allow_future()`]
- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `date_field` [`get_date_field()`]
- `http_method_names`
- `make_object_list` [`get_make_object_list()`]
- `model`
- `ordering` [`get_ordering()`]
- `paginate_by` [`get_paginate_by()`]
- `paginate_orphans` [`get_paginate_orphans()`]
- `paginator_class`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_suffix`
- `year` [`get_year()`]

- `year_format` [`get_year_format()`]

#### Methods

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_date_list()`
- `get_dated_items()`
- `get_dated_queryset()`
- `get_paginator()`
- `head()`
- `http_method_not_allowed()`
- `paginate_queryset()`
- `render_to_response()`

#### MonthArchiveView

##### class MonthArchiveView

##### Attributes (with optional accessor):

- `allow_empty` [`get_allow_empty()`]
- `allow_future` [`get_allow_future()`]
- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `date_field` [`get_date_field()`]
- `http_method_names`
- `model`
- `month` [`get_month()`]
- `month_format` [`get_month_format()`]
- `ordering` [`get_ordering()`]
- `paginate_by` [`get_paginate_by()`]
- `paginate_orphans` [`get_paginate_orphans()`]
- `paginator_class`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]
- `template_name_suffix`

- `year` [`get_year()`]
- `year_format` [`get_year_format()`]

#### Methods

- `as_view()`
- `dispatch()`
- `get()`
- `get_context_data()`
- `get_date_list()`
- `get_dated_items()`
- `get_dated_queryset()`
- `get_next_month()`
- `get_paginator()`
- `get_previous_month()`
- `head()`
- `http_method_not_allowed()`
- `paginate_queryset()`
- `render_to_response()`

#### WeekArchiveView

##### class `WeekArchiveView`

**Attributes** (with optional accessor):

- `allow_empty` [`get_allow_empty()`]
- `allow_future` [`get_allow_future()`]
- `content_type`
- `context_object_name` [`get_context_object_name()`]
- `date_field` [`get_date_field()`]
- `http_method_names`
- `model`
- `ordering` [`get_ordering()`]
- `paginate_by` [`get_paginate_by()`]
- `paginate_orphans` [`get_paginate_orphans()`]
- `paginator_class`
- `queryset` [`get_queryset()`]
- `response_class` [`render_to_response()`]
- `template_engine`
- `template_name` [`get_template_names()`]

- `template_name_suffix`
- `week` [`get_week()`]
- `week_format` [`get_week_format()`]
- `year` [`get_year()`]
- `year_format` [`get_year_format()`]

#### Methods

- `get_object()`
- `get_previous_day()`
- `get_previous_month()`
- `head()`
- `http_method_not_allowed()`

- `render_to_response()`

### 6.3.7 Specification

Each request served by a class-based view has an independent state; therefore, it is safe to store state variables on the instance (i.e., `self.foo = 3` is a thread-safe operation).

A class-based view is deployed into a URL pattern using the `as_view()` classmethod:

```
urlpatterns = [
    url(r'^view/$', MyView.as_view(size=42)),
]
```

---

#### Thread safety with view arguments

Arguments passed to a view are shared between every instance of a view. This means that you shouldn't use a list, dictionary, or any other mutable object as an argument to a view. If you do and the shared object is modified, the actions of one user visiting your view could have an effect on subsequent users visiting the same view.

Arguments passed into `as_view()` will be assigned onto the instance that is used to service a request. Using the previous example, this means that every request on `MyView` is able to use `self.size`. Arguments must correspond to attributes that already exist on the class (return `True` on a `hasattr` check).

### 6.3.8 Base vs Generic views

Base class-based views can be thought of as *parent* views, which can be used by themselves or inherited from. They may not provide all the capabilities required for projects, in which case there are Mixins which extend what base views can do.

Django's generic views are built off of those base views, and were developed as a shortcut for common usage patterns such as displaying the details of an object. They take certain common idioms and patterns found in view development and abstract them so that you can quickly write common views of data without having to repeat yourself.

Most generic views require the `queryset` key, which is a `QuerySet` instance; see *Making queries* for more information about `QuerySet` objects.

## 6.4 Clickjacking Protection

The clickjacking middleware and decorators provide easy-to-use protection against [clickjacking](#). This type of attack occurs when a malicious site tricks a user into clicking on a concealed element of another site which they have loaded in a hidden frame or `iframe`.

### 6.4.1 An example of clickjacking

Suppose an online store has a page where a logged in user can click "Buy Now" to purchase an item. A user has chosen to stay logged into the store all the time for convenience. An attacker site might create an "I Like Ponies" button on one of their own pages, and load the store's page in a transparent `iframe` such that the "Buy Now" button is invisibly overlaid on the "I Like Ponies" button. If the user visits the attacker's site, clicking "I Like Ponies" will cause an inadvertent click on the "Buy Now" button and an unknowing purchase of the item.

## 6.4.2 Preventing clickjacking

Modern browsers honor the `X-Frame-Options` HTTP header that indicates whether or not a resource is allowed to load within a frame or iframe. If the response contains the header with a value of `SAMEORIGIN` then the browser will only load the resource in a frame if the request originated from the same site. If the header is set to `DENY` then the browser will block the resource from loading in a frame no matter which site made the request.

Django provides a few simple ways to include this header in responses from your site:

1. A simple middleware that sets the header in all responses.
2. A set of view decorators that can be used to override the middleware or to only set the header for certain views.

The `X-Frame-Options` HTTP header will only be set by the middleware or view decorators if it is not already present in the response.

## 6.4.3 How to use it

### Setting `X-Frame-Options` for all responses

To set the same `X-Frame-Options` value for all responses in your site, put `'django.middleware.clickjacking.XFrameOptionsMiddleware'` to *MIDDLEWARE*:

```
MIDDLEWARE = [
    ...
    'django.middleware.clickjacking.XFrameOptionsMiddleware',
    ...
]
```

This middleware is enabled in the settings file generated by *startproject*.

By default, the middleware will set the `X-Frame-Options` header to `SAMEORIGIN` for every outgoing `HttpResponse`. If you want `DENY` instead, set the `X_FRAME_OPTIONS` setting:

```
X_FRAME_OPTIONS = 'DENY'
```

When using the middleware there may be some views where you do **not** want the `X-Frame-Options` header set. For those cases, you can use a view decorator that tells the middleware not to set the header:

```
from django.http import HttpResponse
from django.views.decorators.clickjacking import xframe_options_exempt

@xframe_options_exempt
def ok_to_load_in_a_frame(request):
    return HttpResponse("This page is safe to load in a frame on any site.")
```

### Setting `X-Frame-Options` per view

To set the `X-Frame-Options` header on a per view basis, Django provides these decorators:

```
from django.http import HttpResponse
from django.views.decorators.clickjacking import xframe_options_deny
from django.views.decorators.clickjacking import xframe_options_sameorigin

@xframe_options_deny
def view_one(request):
```

```
    return HttpResponse("I won't display in any frame!")

@xframe_options_sameorigin
def view_two(request):
    return HttpResponse("Display in a frame if it's from the same origin as me.")
```

Note that you can use the decorators in conjunction with the middleware. Use of a decorator overrides the middleware.

## 6.4.4 Limitations

The `X-Frame-Options` header will only protect against clickjacking in a modern browser. Older browsers will quietly ignore the header and need [other clickjacking prevention techniques](#).

### Browsers that support `X-Frame-Options`

- Internet Explorer 8+
- Firefox 3.6.9+
- Opera 10.5+
- Safari 4+
- Chrome 4.1+

### See also

A [complete list](#) of browsers supporting `X-Frame-Options`.

## 6.5 contrib packages

Django aims to follow Python’s “[batteries included](#)” philosophy. It ships with a variety of extra, optional tools that solve common Web-development problems.

This code lives in `django/contrib` in the Django distribution. This document gives a rundown of the packages in `contrib`, along with any dependencies those packages have.

---

### Note

For most of these add-ons – specifically, the add-ons that include either models or template tags – you’ll need to add the package name (e.g., `'django.contrib.redirects'`) to your `INSTALLED_APPS` setting and re-run `manage.py migrate`.

---

### 6.5.1 The Django admin site

One of the most powerful parts of Django is the automatic admin interface. It reads metadata from your models to provide a quick, model-centric interface where trusted users can manage content on your site. The admin’s recommended use is limited to an organization’s internal management tool. It’s not intended for building your entire front end around.

The admin has many hooks for customization, but beware of trying to use those hooks exclusively. If you need to provide a more process-centric interface that abstracts away the implementation details of database tables and fields, then it's probably time to write your own views.

In this document we discuss how to activate, use, and customize Django's admin interface.

## Overview

The admin is enabled in the default project template used by `startproject`.

For reference, here are the requirements:

1. Add `'django.contrib.admin'` to your `INSTALLED_APPS` setting.
2. The admin has four dependencies - `django.contrib.auth`, `django.contrib.contenttypes`, `django.contrib.messages` and `django.contrib.sessions`. If these applications are not in your `INSTALLED_APPS` list, add them.
3. Add `django.contrib.auth.context_processors.auth` and `django.contrib.messages.context_processors.messages` to the `'context_processors'` option of the DjangoTemplates backend defined in your `TEMPLATES` as well as `django.contrib.auth.middleware.AuthenticationMiddleware` and `django.contrib.messages.middleware.MessageMiddleware` to `MIDDLEWARE`. These are all active by default, so you only need to do this if you've manually tweaked the settings.
4. Determine which of your application's models should be editable in the admin interface.
5. For each of those models, optionally create a `ModelAdmin` class that encapsulates the customized admin functionality and options for that particular model.
6. Instantiate an `AdminSite` and tell it about each of your models and `ModelAdmin` classes.
7. Hook the `AdminSite` instance into your URLconf.

After you've taken these steps, you'll be able to use your Django admin site by visiting the URL you hooked it into (`/admin/`, by default). If you need to create a user to login with, you can use the `createsuperuser` command.

## Other topics

### Admin actions

The basic workflow of Django's admin is, in a nutshell, "select an object, then change it." This works well for a majority of use cases. However, if you need to make the same change to many objects at once, this workflow can be quite tedious.

In these cases, Django's admin lets you write and register "actions" – simple functions that get called with a list of objects selected on the change list page.

If you look at any change list in the admin, you'll see this feature in action; Django ships with a "delete selected objects" action available to all models. For example, here's the user module from Django's built-in `django.contrib.auth` app:

Select user to change

Q  Search

Action:  ----- Go 1 of 3 selected  
Delete selected users

<input type="checkbox"/>	USERNAME	EMAIL ADDRESS	FIRST NAME	LAST NAME	STAFF STATUS
<input checked="" type="checkbox"/>	adrian	adrian@example.com	Adrian	Holovaty	✖
<input type="checkbox"/>	jacob	jacob@example.com	Jacob	Kaplan-Moss	✔
<input type="checkbox"/>	simon	simon@example.com	Simon	Willison	✖

3 users

**Warning:** The “delete selected objects” action uses `QuerySet.delete()` for efficiency reasons, which has an important caveat: your model’s `delete()` method will not be called.

If you wish to override this behavior, simply write a custom action which accomplishes deletion in your preferred manner – for example, by calling `Model.delete()` for each of the selected items.

For more background on bulk deletion, see the documentation on [object deletion](#).

Read on to find out how to add your own actions to this list.

## Writing actions

The easiest way to explain actions is by example, so let’s dive in.

A common use case for admin actions is the bulk updating of a model. Imagine a simple news application with an `Article` model:

```
from django.db import models

STATUS_CHOICES = (
    ('d', 'Draft'),
    ('p', 'Published'),
    ('w', 'Withdrawn'),
)

class Article(models.Model):
    title = models.CharField(max_length=100)
    body = models.TextField()
    status = models.CharField(max_length=1, choices=STATUS_CHOICES)

    def __str__(self):
        return self.title
```

A common task we might perform with a model like this is to update an article’s status from “draft” to “published”. We could easily do this in the admin one article at a time, but if we wanted to bulk-publish a group of articles, it’d be tedious. So, let’s write an action that lets us change an article’s status to “published.”

## Writing action functions

First, we'll need to write a function that gets called when the action is triggered from the admin. Action functions are just regular functions that take three arguments:

- The current *ModelAdmin*
- An *HttpRequest* representing the current request,
- A *QuerySet* containing the set of objects selected by the user.

Our publish-these-articles function won't need the *ModelAdmin* or the request object, but we will use the queryset:

```
def make_published(modeladmin, request, queryset):
    queryset.update(status='p')
```

**Note:** For the best performance, we're using the queryset's *update method*. Other types of actions might need to deal with each object individually; in these cases we'd just iterate over the queryset:

```
for obj in queryset:
    do_something_with(obj)
```

That's actually all there is to writing an action! However, we'll take one more optional-but-useful step and give the action a "nice" title in the admin. By default, this action would appear in the action list as "Make published" – the function name, with underscores replaced by spaces. That's fine, but we can provide a better, more human-friendly name by giving the `make_published` function a `short_description` attribute:

```
def make_published(modeladmin, request, queryset):
    queryset.update(status='p')
make_published.short_description = "Mark selected stories as published"
```

**Note:** This might look familiar; the admin's `list_display` option uses the same technique to provide human-readable descriptions for callback functions registered there, too.

## Adding actions to the ModelAdmin

Next, we'll need to inform our *ModelAdmin* of the action. This works just like any other configuration option. So, the complete `admin.py` with the action and its registration would look like:

```
from django.contrib import admin
from myapp.models import Article

def make_published(modeladmin, request, queryset):
    queryset.update(status='p')
make_published.short_description = "Mark selected stories as published"

class ArticleAdmin(admin.ModelAdmin):
    list_display = ['title', 'status']
    ordering = ['title']
    actions = [make_published]

admin.site.register(Article, ArticleAdmin)
```

That code will give us an admin change list that looks something like this:

That's really all there is to it! If you're itching to write your own actions, you now know enough to get started. The rest of this document just covers more advanced techniques.

## Handling errors in actions

If there are foreseeable error conditions that may occur while running your action, you should gracefully inform the user of the problem. This means handling exceptions and using `django.contrib.admin.ModelAdmin.message_user()` to display a user friendly description of the problem in the response.

## Advanced action techniques

There's a couple of extra options and possibilities you can exploit for more advanced options.

## Actions as `ModelAdmin` methods

The example above shows the `make_published` action defined as a simple function. That's perfectly fine, but it's not perfect from a code design point of view: since the action is tightly coupled to the `Article` object, it makes sense to hook the action to the `ArticleAdmin` object itself.

That's easy enough to do:

```
class ArticleAdmin(admin.ModelAdmin):
    ...

    actions = ['make_published']

    def make_published(self, request, queryset):
        queryset.update(status='p')
    make_published.short_description = "Mark selected stories as published"
```

Notice first that we've moved `make_published` into a method and renamed the `modeladmin` parameter to `self`, and second that we've now put the string `'make_published'` in `actions` instead of a direct function reference. This tells the `ModelAdmin` to look up the action as a method.

Defining actions as methods gives the action more straightforward, idiomatic access to the `ModelAdmin` itself, allowing the action to call any of the methods provided by the admin. For example, we can use `self` to flash a message to the user informing her that the action was successful:

```
class ArticleAdmin(admin.ModelAdmin):
    ...

    def make_published(self, request, queryset):
        rows_updated = queryset.update(status='p')
        if rows_updated == 1:
            message_bit = "1 story was"
        else:
            message_bit = "%s stories were" % rows_updated
        self.message_user(request, "%s successfully marked as published." % message_
↵bit)
```

This make the action match what the admin itself does after successfully performing an action:

The screenshot shows the Django administration interface. At the top, it says "Django administration" and "WELCOME, RYAN. VIEW SITE / CHANGE PASSWORD / LOG OUT". Below that, there's a breadcrumb trail: "Home > News > Articles". A green message box at the top says "2 stories were successfully marked as published." Below that, there's a section titled "Select article to change" with an "ADD ARTICLE +" button. Underneath, there's an "Action:" dropdown menu, a "Go" button, and "0 of 5 selected". A table of articles is shown below:

<input type="checkbox"/>	TITLE	STATUS
<input type="checkbox"/>	A New Human-like Species Discovered in Deep Burial Chamber	Published
<input type="checkbox"/>	Django 1.9 Released	Published
<input type="checkbox"/>	Mars Is a Real Fixer-Upper of a Planet, Says Elon Musk on Colbert's 'Late Show'	Withdrawn
<input type="checkbox"/>	The Coming of the Glacier Men	Published

## Actions that provide intermediate pages

By default, after an action is performed the user is simply redirected back to the original change list page. However, some actions, especially more complex ones, will need to return intermediate pages. For example, the built-in delete action asks for confirmation before deleting the selected objects.

To provide an intermediary page, simply return an `HttpResponse` (or subclass) from your action. For example, you might write a simple export function that uses Django's *serialization functions* to dump some selected objects as JSON:

```
from django.http import HttpResponse
from django.core import serializers

def export_as_json(modeladmin, request, queryset):
    response = HttpResponse(content_type="application/json")
    serializers.serialize("json", queryset, stream=response)
    return response
```

Generally, something like the above isn't considered a great idea. Most of the time, the best practice will be to return an `HttpResponseRedirect` and redirect the user to a view you've written, passing the list of selected objects in the GET query string. This allows you to provide complex interaction logic on the intermediary pages. For example, if you wanted to provide a more complete export function, you'd want to let the user choose a format, and possibly a list of fields to include in the export. The best thing to do would be to write a small action that simply redirects to your custom export view:

```
from django.contrib import admin
from django.contrib.contenttypes.models import ContentType
from django.http import HttpResponseRedirect

def export_selected_objects(modeladmin, request, queryset):
    selected = request.POST.getlist(admin.ACTION_CHECKBOX_NAME)
    ct = ContentType.objects.get_for_model(queryset.model)
    return HttpResponseRedirect("/export/?ct=%s&ids=%s" % (ct.pk, ",".join(selected)))
```

As you can see, the action is the simple part; all the complex logic would belong in your export view. This would need to deal with objects of any type, hence the business with the `ContentType`.

Writing this view is left as an exercise to the reader.

## Making actions available site-wide

`AdminSite.add_action(action, name=None)`

Some actions are best if they're made available to *any* object in the admin site – the export action defined above would be a good candidate. You can make an action globally available using `AdminSite.add_action()`. For example:

```
from django.contrib import admin

admin.site.add_action(export_selected_objects)
```

This makes the `export_selected_objects` action globally available as an action named “`export_selected_objects`”. You can explicitly give the action a name – good if you later want to programmatically *remove the action* – by passing a second argument to `AdminSite.add_action()`:

```
admin.site.add_action(export_selected_objects, 'export_selected')
```

## Disabling actions

Sometimes you need to disable certain actions – especially those *registered site-wide* – for particular objects. There's a few ways you can disable actions:

### Disabling a site-wide action

`AdminSite.disable_action(name)`

If you need to disable a *site-wide action* you can call `AdminSite.disable_action()`.

For example, you can use this method to remove the built-in “delete selected objects” action:

```
admin.site.disable_action('delete_selected')
```

Once you've done the above, that action will no longer be available site-wide.

If, however, you need to re-enable a globally-disabled action for one particular model, simply list it explicitly in your `ModelAdmin.actions` list:

```
# Globally disable delete_selected
admin.site.disable_action('delete_selected')

# This ModelAdmin will not have delete_selected available
class SomeModelAdmin(admin.ModelAdmin):
    actions = ['some_other_action']
    ...

# This one will
class AnotherModelAdmin(admin.ModelAdmin):
    actions = ['delete_selected', 'a_third_action']
    ...
```

### Disabling all actions for a particular ModelAdmin

If you want *no* bulk actions available for a given *ModelAdmin*, simply set *ModelAdmin.actions* to `None`:

```
class MyModelAdmin(admin.ModelAdmin):
    actions = None
```

This tells the *ModelAdmin* to not display or allow any actions, including any *site-wide actions*.

### Conditionally enabling or disabling actions

`ModelAdmin.get_actions(request)`

Finally, you can conditionally enable or disable actions on a per-request (and hence per-user basis) by overriding `ModelAdmin.get_actions()`.

This returns a dictionary of actions allowed. The keys are action names, and the values are (function, name, short\_description) tuples.

Most of the time you'll use this method to conditionally remove actions from the list gathered by the superclass. For example, if I only wanted users whose names begin with 'J' to be able to delete objects in bulk, I could do the following:

```
class MyModelAdmin(admin.ModelAdmin):
    ...

    def get_actions(self, request):
        actions = super(MyModelAdmin, self).get_actions(request)
        if request.user.username[0].upper() != 'J':
            if 'delete_selected' in actions:
                del actions['delete_selected']
        return actions
```

### The Django admin documentation generator

Django's `admin_docs` app pulls documentation from the docstrings of models, views, template tags, and template filters for any app in `INSTALLED_APPS` and makes that documentation available from the *Django admin*.

## Overview

To activate the `admindocs`, you will need to do the following:

- Add `django.contrib.admindocs` to your `INSTALLED_APPS`.
- Add `url(r'^admin/doc/', include('django.contrib.admindocs.urls'))` to your `urlpatterns`. Make sure it's included *before* the `r'^admin/'` entry, so that requests to `/admin/doc/` don't get handled by the latter entry.
- Install the `docutils` Python module (<http://docutils.sf.net/>).
- **Optional:** Using the `admindocs` bookmarklets requires `django.contrib.admindocs.middleware.XViewMiddleware` to be installed.

Once those steps are complete, you can start browsing the documentation by going to your admin interface and clicking the “Documentation” link in the upper right of the page.

## Documentation helpers

The following special markup can be used in your docstrings to easily create hyperlinks to other components:

Django Component	reStructuredText roles
Models	<code>:model:`app_label.ModelName`</code>
Views	<code>:view:`app_label.view_name`</code>
Template tags	<code>:tag:`tagname`</code>
Template filters	<code>:filter:`filtername`</code>
Templates	<code>:template:`path/to/template.html`</code>

## Model reference

The **models** section of the `admindocs` page describes each model in the system along with all the fields and methods available on it. Relationships to other models appear as hyperlinks. Descriptions are pulled from `help_text` attributes on fields or from docstrings on model methods.

The **models** section of the `admindocs` now describes methods that take arguments as well. In previous versions it was restricted to methods without arguments.

A model with useful documentation might look like this:

```
class BlogEntry(models.Model):
    """
    Stores a single blog entry, related to :model:`blog.Blog` and
    :model:`auth.User`.
    """
    slug = models.SlugField(help_text="A short label, generally used in URLs.")
    author = models.ForeignKey(
        User,
        models.SET_NULL,
        blank=True, null=True,
    )
    blog = models.ForeignKey(Blog, models.CASCADE)
    ...

    def publish(self):
        """Makes the blog entry live on the site."""
        ...
```

## View reference

Each URL in your site has a separate entry in the `admindocs` page, and clicking on a given URL will show you the corresponding view. Helpful things you can document in your view function docstrings include:

- A short description of what the view does.
- The **context**, or a list of variables available in the view's template.
- The name of the template or templates that are used for that view.

For example:

```
from django.shortcuts import render

from myapp.models import MyModel

def my_view(request, slug):
    """
    Display an individual :model:`myapp.MyModel`.

    **Context**

    ``mymodel``
        An instance of :model:`myapp.MyModel`.

    **Template:**

    :template:`myapp/my_template.html`
    """
    context = {'mymodel': MyModel.objects.get(slug=slug)}
    return render(request, 'myapp/my_template.html', context)
```

## Template tags and filters reference

The **tags** and **filters** `admindocs` sections describe all the tags and filters that come with Django (in fact, the *built-in tag reference* and *built-in filter reference* documentation come directly from those pages). Any tags or filters that you create or are added by a third-party app will show up in these sections as well.

## Template reference

While `admindocs` does not include a place to document templates by themselves, if you use the `:template:`path/to/template.html`` syntax in a docstring the resulting page will verify the path of that template with Django's *template loaders*. This can be a handy way to check if the specified template exists and to show where on the filesystem that template is stored.

## Included Bookmarklets

One bookmarklet is available from the `admindocs` page:

**Documentation for this page** Jumps you from any page to the documentation for the view that generates that page.

Using this bookmarklet requires that `XViewMiddleware` is installed and that you are logged into the *Django admin* as a *User* with `is_staff` set to `True`.

## JavaScript customizations in the admin

### Inline form events

You may want to execute some JavaScript when an inline form is added or removed in the admin change form. The `formset:added` and `formset:removed` jQuery events allow this. The event handler is passed three arguments:

- `event` is the jQuery event.
- `$row` is the newly added (or removed) row.
- `formsetName` is the formset the row belongs to.

The event is fired using the `django.jQuery namespace`.

In your custom `change_form.html` template, extend the `admin_change_form_document_ready` block and add the event listener code:

```
{% extends 'admin/change_form.html' %}
{% load static %}

{% block admin_change_form_document_ready %}
{{ block.super }}
<script type="text/javascript" src="{% static 'app/formset_handlers.js' %}"></script>
{% endblock %}
```

```
app/static/app/formset_handlers.js
```

```
(function($) {
    $(document).on('formset:added', function(event, $row, formsetName) {
        if (formsetName == 'author_set') {
            // Do something
        }
    });

    $(document).on('formset:removed', function(event, $row, formsetName) {
        // Row removed
    });
})(django.jQuery);
```

Two points to keep in mind:

- The JavaScript code must go in a template block if you are inheriting `admin/change_form.html` or it won't be rendered in the final HTML.
- `{{ block.super }}` is added because Django's `admin_change_form_document_ready` block contains JavaScript code to handle various operations in the change form and we need that to be rendered too.

Sometimes you'll need to work with jQuery plugins that are not registered in the `django.jQuery namespace`. To do that, simply change how the code listens for events. Instead of wrapping the listener in the `django.jQuery namespace`, just listen to the event triggered from there. For example:

```
{% extends 'admin/change_form.html' %}
{% load static %}

{% block admin_change_form_document_ready %}
{{ block.super }}
<script type="text/javascript" src="{% static 'app/unregistered_handlers.js' %}"></
<script>
{% endblock %}
```

```
app/static/app/unregistered_handlers.js
```

```
django.jQuery(document).on('formset:added', function(event, $row, formsetName) {
    // Row added
});

django.jQuery(document).on('formset:removed', function(event, $row, formsetName) {
    // Row removed
});
```

**ModelAdmin objects****class ModelAdmin**

The `ModelAdmin` class is the representation of a model in the admin interface. Usually, these are stored in a file named `admin.py` in your application. Let's take a look at a very simple example of the `ModelAdmin`:

```
from django.contrib import admin
from myproject.myapp.models import Author

class AuthorAdmin(admin.ModelAdmin):
    pass
admin.site.register(Author, AuthorAdmin)
```

**Do you need a ModelAdmin object at all?**

In the preceding example, the `ModelAdmin` class doesn't define any custom values (yet). As a result, the default admin interface will be provided. If you are happy with the default admin interface, you don't need to define a `ModelAdmin` object at all – you can register the model class without providing a `ModelAdmin` description. The preceding example could be simplified to:

```
from django.contrib import admin
from myproject.myapp.models import Author

admin.site.register(Author)
```

**The register decorator**

**register** (\*models, site=`django.admin.sites.site`)

There is also a decorator for registering your `ModelAdmin` classes:

```
from django.contrib import admin
from .models import Author

@admin.register(Author)
class AuthorAdmin(admin.ModelAdmin):
    pass
```

It is given one or more model classes to register with the `ModelAdmin` and an optional keyword argument `site` if you are not using the default `AdminSite`:

```
from django.contrib import admin
from .models import Author, Reader, Editor
from myproject.admin_site import custom_admin_site

@admin.register(Author, Reader, Editor, site=custom_admin_site)
class PersonAdmin(admin.ModelAdmin):
    pass
```

You can't use this decorator if you have to reference your model admin class in its `__init__()` method, e.g. `super(PersonAdmin, self).__init__(*args, **kwargs)`. If you are using Python 3 and don't have to worry about supporting Python 2, you can use `super().__init__(*args, **kwargs)`. Otherwise, you'll have to use `admin.site.register()` instead of this decorator.

## Discovery of admin files

When you put `'django.contrib.admin'` in your `INSTALLED_APPS` setting, Django automatically looks for an admin module in each application and imports it.

### `class apps.AdminConfig`

This is the default `AppConfig` class for the admin. It calls `autodiscover()` when Django starts.

### `class apps.SimpleAdminConfig`

This class works like `AdminConfig`, except it doesn't call `autodiscover()`.

### `autodiscover()`

This function attempts to import an admin module in each installed application. Such modules are expected to register models with the admin.

Typically you won't need to call this function directly as `AdminConfig` calls it when Django starts.

If you are using a custom `AdminSite`, it is common to import all of the `ModelAdmin` subclasses into your code and register them to the custom `AdminSite`. In that case, in order to disable auto-discovery, you should put `'django.contrib.admin.apps.SimpleAdminConfig'` instead of `'django.contrib.admin'` in your `INSTALLED_APPS` setting.

## ModelAdmin options

The `ModelAdmin` is very flexible. It has several options for dealing with customizing the interface. All options are defined on the `ModelAdmin` subclass:

```
from django.contrib import admin

class AuthorAdmin(admin.ModelAdmin):
    date_hierarchy = 'pub_date'
```

### `ModelAdmin.actions`

A list of actions to make available on the change list page. See *Admin actions* for details.

### `ModelAdmin.actions_on_top`

### `ModelAdmin.actions_on_bottom`

Controls where on the page the actions bar appears. By default, the admin changelist displays actions at the top of the page (`actions_on_top = True`; `actions_on_bottom = False`).

**ModelAdmin.actions\_selection\_counter**

Controls whether a selection counter is displayed next to the action dropdown. By default, the admin changelist will display it (`actions_selection_counter = True`).

**ModelAdmin.date\_hierarchy**

Set `date_hierarchy` to the name of a `DateField` or `DateTimeField` in your model, and the change list page will include a date-based drilldown navigation by that field.

Example:

```
date_hierarchy = 'pub_date'
```

This will intelligently populate itself based on available data, e.g. if all the dates are in one month, it'll show the day-level drill-down only.

**Note:** `date_hierarchy` uses `QuerySet.dates()` internally. Please refer to its documentation for some caveats when time zone support is enabled (`USE_TZ = True`).

**ModelAdmin.empty\_value\_display**

This attribute overrides the default display value for record's fields that are empty (None, empty string, etc.). The default value is – (a dash). For example:

```
from django.contrib import admin

class AuthorAdmin(admin.ModelAdmin):
    empty_value_display = '-empty-'
```

You can also override `empty_value_display` for all admin pages with `AdminSite.empty_value_display`, or for specific fields like this:

```
from django.contrib import admin

class AuthorAdmin(admin.ModelAdmin):
    fields = ('name', 'title', 'view_birth_date')

    def view_birth_date(self, obj):
        return obj.birth_date

    view_birth_date.empty_value_display = '???'
```

**ModelAdmin.exclude**

This attribute, if given, should be a list of field names to exclude from the form.

For example, let's consider the following model:

```
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=100)
    title = models.CharField(max_length=3)
    birth_date = models.DateField(blank=True, null=True)
```

If you want a form for the `Author` model that includes only the name and title fields, you would specify fields or exclude like this:

```
from django.contrib import admin
```

```
class AuthorAdmin(admin.ModelAdmin):
    fields = ('name', 'title')

class AuthorAdmin(admin.ModelAdmin):
    exclude = ('birth_date',)
```

Since the Author model only has three fields, name, title, and birth\_date, the forms resulting from the above declarations will contain exactly the same fields.

#### ModelAdmin.fields

Use the `fields` option to make simple layout changes in the forms on the “add” and “change” pages such as showing only a subset of available fields, modifying their order, or grouping them into rows. For example, you could define a simpler version of the admin form for the `django.contrib.flatpages.models.FlatPage` model as follows:

```
class FlatPageAdmin(admin.ModelAdmin):
    fields = ('url', 'title', 'content')
```

In the above example, only the fields `url`, `title` and `content` will be displayed, sequentially, in the form. fields can contain values defined in `ModelAdmin.readonly_fields` to be displayed as read-only.

For more complex layout needs, see the `fieldsets` option.

The `fields` option, unlike `list_display`, may only contain names of fields on the model or the form specified by `form`. It may contain callables only if they are listed in `readonly_fields`.

To display multiple fields on the same line, wrap those fields in their own tuple. In this example, the `url` and `title` fields will display on the same line and the `content` field will be displayed below them on its own line:

```
class FlatPageAdmin(admin.ModelAdmin):
    fields = (('url', 'title'), 'content')
```

---

#### Note

This `fields` option should not be confused with the `fields` dictionary key that is within the `fieldsets` option, as described in the next section.

---

If neither `fields` nor `fieldsets` options are present, Django will default to displaying each field that isn't an `AutoField` and has `editable=True`, in a single fieldset, in the same order as the fields are defined in the model.

#### ModelAdmin.fieldsets

Set `fieldsets` to control the layout of admin “add” and “change” pages.

`fieldsets` is a list of two-tuples, in which each two-tuple represents a `<fieldset>` on the admin form page. (A `<fieldset>` is a “section” of the form.)

The two-tuples are in the format `(name, field_options)`, where `name` is a string representing the title of the fieldset and `field_options` is a dictionary of information about the fieldset, including a list of fields to be displayed in it.

A full example, taken from the `django.contrib.flatpages.models.FlatPage` model:

```
from django.contrib import admin

class FlatPageAdmin(admin.ModelAdmin):
    fieldsets = (
```

```
(None, {
    'fields': ('url', 'title', 'content', 'sites')
}),
('Advanced options', {
    'classes': ('collapse',),
    'fields': ('registration_required', 'template_name'),
}),
)
```

This results in an admin page that looks like:

Add flat page

URL:   
Example: '/about/contact/'. Make sure to have leading and trailing slashes.

---

Title:

---

Content:

---

Sites: 

example.com

 +

Hold down "Control", or "Command" on a Mac, to select more than one.

---

Advanced options ([Show](#))

---

If neither `fieldsets` nor `fields` options are present, Django will default to displaying each field that isn't an `AutoField` and has `editable=True`, in a single fieldset, in the same order as the fields are defined in the model.

The `field_options` dictionary can have the following keys:

- **fields** A tuple of field names to display in this fieldset. This key is required.

Example:

```
{
    'fields': ('first_name', 'last_name', 'address', 'city', 'state'),
}
```

As with the `fields` option, to display multiple fields on the same line, wrap those fields in their own tuple. In this example, the `first_name` and `last_name` fields will display on the same line:

```
{
  'fields': (('first_name', 'last_name'), 'address', 'city', 'state'),
}
```

`fields` can contain values defined in `readonly_fields` to be displayed as read-only.

If you add the name of a callable to `fields`, the same rule applies as with the `fields` option: the callable must be listed in `readonly_fields`.

- **classes** A list or tuple containing extra CSS classes to apply to the fieldset.

Example:

```
{
  'classes': ('wide', 'extrapretty'),
}
```

Two useful classes defined by the default admin site stylesheet are `collapse` and `wide`. Fieldsets with the `collapse` style will be initially collapsed in the admin and replaced with a small “click to expand” link. Fieldsets with the `wide` style will be given extra horizontal space.

- **description** A string of optional extra text to be displayed at the top of each fieldset, under the heading of the fieldset. This string is not rendered for `TabularInline` due to its layout.

Note that this value is *not* HTML-escaped when it’s displayed in the admin interface. This lets you include HTML if you so desire. Alternatively you can use plain text and `django.utils.html.escape()` to escape any HTML special characters.

#### `ModelAdmin.filter_horizontal`

By default, a `ManyToManyField` is displayed in the admin site with a `<select multiple>`. However, multiple-select boxes can be difficult to use when selecting many items. Adding a `ManyToManyField` to this list will instead use a nifty unobtrusive JavaScript “filter” interface that allows searching within the options. The unselected and selected options appear in two boxes side by side. See `filter_vertical` to use a vertical interface.

#### `ModelAdmin.filter_vertical`

Same as `filter_horizontal`, but uses a vertical display of the filter interface with the box of unselected options appearing above the box of selected options.

#### `ModelAdmin.form`

By default a `ModelForm` is dynamically created for your model. It is used to create the form presented on both the add/change pages. You can easily provide your own `ModelForm` to override any default form behavior on the add/change pages. Alternatively, you can customize the default form rather than specifying an entirely new one by using the `ModelAdmin.get_form()` method.

For an example see the section [Adding custom validation to the admin](#).

---

#### Note

If you define the `Meta.model` attribute on a `ModelForm`, you must also define the `Meta.fields` attribute (or the `Meta.exclude` attribute). However, since the admin has its own way of defining fields, the `Meta.fields` attribute will be ignored.

If the `ModelForm` is only going to be used for the admin, the easiest solution is to omit the `Meta.model` attribute, since `ModelAdmin` will provide the correct model to use. Alternatively, you can set `fields = []` in the `Meta` class to satisfy the validation on the `ModelForm`.

---

---

## Note

If your `ModelForm` and `ModelAdmin` both define an `exclude` option then `ModelAdmin` takes precedence:

```

from django import forms
from django.contrib import admin
from myapp.models import Person

class PersonForm(forms.ModelForm):

    class Meta:
        model = Person
        exclude = ['name']

class PersonAdmin(admin.ModelAdmin):
    exclude = ['age']
    form = PersonForm

```

In the above example, the “age” field will be excluded but the “name” field will be included in the generated form.

---

## ModelAdmin.`formfield_overrides`

This provides a quick-and-dirty way to override some of the `Field` options for use in the admin. `formfield_overrides` is a dictionary mapping a field class to a dict of arguments to pass to the field at construction time.

Since that’s a bit abstract, let’s look at a concrete example. The most common use of `formfield_overrides` is to add a custom widget for a certain type of field. So, imagine we’ve written a `RichTextEditorWidget` that we’d like to use for large text fields instead of the default `<textarea>`. Here’s how we’d do that:

```

from django.db import models
from django.contrib import admin

# Import our custom widget and our model from where they're defined
from myapp.widgets import RichTextEditorWidget
from myapp.models import MyModel

class MyModelAdmin(admin.ModelAdmin):
    formfield_overrides = {
        models.TextField: {'widget': RichTextEditorWidget},
    }

```

Note that the key in the dictionary is the actual field class, *not* a string. The value is another dictionary; these arguments will be passed to the form field’s `__init__()` method. See [The Forms API](#) for details.

**Warning:** If you want to use a custom widget with a relation field (i.e. `ForeignKey` or `ManyToManyField`), make sure you haven’t included that field’s name in `raw_id_fields` or `radio_fields`.

`formfield_overrides` won’t let you change the widget on relation fields that have `raw_id_fields` or `radio_fields` set. That’s because `raw_id_fields` and `radio_fields` imply custom widgets of their own.

## ModelAdmin.`inlines`

See `InlineModelAdmin` objects below as well as `ModelAdmin.get_formsets_with_inlines()`.

### `ModelAdmin.list_display`

Set `list_display` to control which fields are displayed on the change list page of the admin.

Example:

```
list_display = ('first_name', 'last_name')
```

If you don't set `list_display`, the admin site will display a single column that displays the `__str__()` (`__unicode__()` on Python 2) representation of each object.

You have four possible values that can be used in `list_display`:

- A field of the model. For example:

```
class PersonAdmin(admin.ModelAdmin):
    list_display = ('first_name', 'last_name')
```

- A callable that accepts one parameter for the model instance. For example:

```
def upper_case_name(obj):
    return ("%s %s" % (obj.first_name, obj.last_name)).upper()
upper_case_name.short_description = 'Name'

class PersonAdmin(admin.ModelAdmin):
    list_display = (upper_case_name,)
```

- A string representing an attribute on the `ModelAdmin`. This behaves same as the callable. For example:

```
class PersonAdmin(admin.ModelAdmin):
    list_display = ('upper_case_name',)

    def upper_case_name(self, obj):
        return ("%s %s" % (obj.first_name, obj.last_name)).upper()
    upper_case_name.short_description = 'Name'
```

- A string representing an attribute on the model. This behaves almost the same as the callable, but `self` in this context is the model instance. Here's a full model example:

```
from django.db import models
from django.contrib import admin

class Person(models.Model):
    name = models.CharField(max_length=50)
    birthday = models.DateField()

    def decade_born_in(self):
        return self.birthday.strftime('%Y')[:3] + "0's"
    decade_born_in.short_description = 'Birth decade'

class PersonAdmin(admin.ModelAdmin):
    list_display = ('name', 'decade_born_in')
```

A few special cases to note about `list_display`:

- If the field is a `ForeignKey`, Django will display the `__str__()` (`__unicode__()` on Python 2) of the related object.

- ManyToManyField fields aren't supported, because that would entail executing a separate SQL statement for each row in the table. If you want to do this nonetheless, give your model a custom method, and add that method's name to `list_display`. (See below for more on custom methods in `list_display`.)
- If the field is a `BooleanField` or `NullBooleanField`, Django will display a pretty “on” or “off” icon instead of `True` or `False`.
- If the string given is a method of the model, `ModelAdmin` or a callable, Django will HTML-escape the output by default. To escape user input and allow your own unescaped tags, use `format_html()`.

Here's a full example model:

```
from django.db import models
from django.contrib import admin
from django.utils.html import format_html

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)
    color_code = models.CharField(max_length=6)

    def colored_name(self):
        return format_html(
            '<span style="color: #{};">{} {}</span>',
            self.color_code,
            self.first_name,
            self.last_name,
        )

class PersonAdmin(admin.ModelAdmin):
    list_display = ('first_name', 'last_name', 'colored_name')
```

Deprecated since version 1.9: In older versions, you could add an `allow_tags` attribute to the method to prevent auto-escaping. This attribute is deprecated as it's safer to use `format_html()`, `format_html_join()`, or `mark_safe()` instead.

- As some examples have already demonstrated, when using a callable, a model method, or a `ModelAdmin` method, you can customize the column's title by adding a `short_description` attribute to the callable.
- If the value of a field is `None`, an empty string, or an iterable without elements, Django will display – (a dash). You can override this with `AdminSite.empty_value_display`:

```
from django.contrib import admin

admin.site.empty_value_display = '(None)'
```

You can also use `ModelAdmin.empty_value_display`:

```
class PersonAdmin(admin.ModelAdmin):
    empty_value_display = 'unknown'
```

Or on a field level:

```
class PersonAdmin(admin.ModelAdmin):
    list_display = ('name', 'birth_date_view')

    def birth_date_view(self, obj):
```

```
        return obj.birth_date

    birth_date_view.empty_value_display = 'unknown'
```

The ability to customize `empty_value_display` was added.

- If the string given is a method of the model, `ModelAdmin` or a callable that returns `True` or `False` Django will display a pretty “on” or “off” icon if you give the method a boolean attribute whose value is `True`.

Here’s a full example model:

```
from django.db import models
from django.contrib import admin

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    birthday = models.DateField()

    def born_in_fifties(self):
        return self.birthday.strftime('%Y')[:3] == '195'
    born_in_fifties.boolean = True

class PersonAdmin(admin.ModelAdmin):
    list_display = ('name', 'born_in_fifties')
```

- The `__str__()` (`__unicode__()` on Python 2) method is just as valid in `list_display` as any other model method, so it’s perfectly OK to do this:

```
list_display = ('__str__', 'some_other_field')
```

- Usually, elements of `list_display` that aren’t actual database fields can’t be used in sorting (because Django does all the sorting at the database level).

However, if an element of `list_display` represents a certain database field, you can indicate this fact by setting the `admin_order_field` attribute of the item.

For example:

```
from django.db import models
from django.contrib import admin
from django.utils.html import format_html

class Person(models.Model):
    first_name = models.CharField(max_length=50)
    color_code = models.CharField(max_length=6)

    def colored_first_name(self):
        return format_html(
            '<span style="color: #{};">{}</span>',
            self.color_code,
            self.first_name,
        )

    colored_first_name.admin_order_field = 'first_name'

class PersonAdmin(admin.ModelAdmin):
    list_display = ('first_name', 'colored_first_name')
```

The above will tell Django to order by the `first_name` field when trying to sort by `colored_first_name` in the admin.

To indicate descending order with `admin_order_field` you can use a hyphen prefix on the field name. Using the above example, this would look like:

```
colored_first_name.admin_order_field = '-first_name'
```

`admin_order_field` supports query lookups to sort by values on related models. This example includes an “author first name” column in the list display and allows sorting it by first name:

```
class Blog(models.Model):
    title = models.CharField(max_length=255)
    author = models.ForeignKey(Person, on_delete=models.CASCADE)

class BlogAdmin(admin.ModelAdmin):
    list_display = ('title', 'author', 'author_first_name')

    def author_first_name(self, obj):
        return obj.author.first_name

    author_first_name.admin_order_field = 'author__first_name'
```

- Elements of `list_display` can also be properties. Please note however, that due to the way properties work in Python, setting `short_description` on a property is only possible when using the `property()` function and **not** with the `@property` decorator.

For example:

```
class Person(models.Model):
    first_name = models.CharField(max_length=50)
    last_name = models.CharField(max_length=50)

    def my_property(self):
        return self.first_name + ' ' + self.last_name
    my_property.short_description = "Full name of the person"

    full_name = property(my_property)

class PersonAdmin(admin.ModelAdmin):
    list_display = ('full_name',)
```

- The field names in `list_display` will also appear as CSS classes in the HTML output, in the form of `column-<field_name>` on each `<th>` element. This can be used to set column widths in a CSS for example.
- Django will try to interpret every element of `list_display` in this order:
  - A field of the model.
  - A callable.
  - A string representing a `ModelAdmin` attribute.
  - A string representing a model attribute.

For example if you have `first_name` as a model field and as a `ModelAdmin` attribute, the model field will be used.

#### `ModelAdmin.list_display_links`

Use `list_display_links` to control if and which fields in `list_display` should be linked to the

“change” page for an object.

By default, the change list page will link the first column – the first field specified in `list_display` – to the change page for each item. But `list_display_links` lets you change this:

- Set it to `None` to get no links at all.
- Set it to a list or tuple of fields (in the same format as `list_display`) whose columns you want converted to links.

You can specify one or many fields. As long as the fields appear in `list_display`, Django doesn’t care how many (or how few) fields are linked. The only requirement is that if you want to use `list_display_links` in this fashion, you must define `list_display`.

In this example, the `first_name` and `last_name` fields will be linked on the change list page:

```
class PersonAdmin(admin.ModelAdmin):
    list_display = ('first_name', 'last_name', 'birthday')
    list_display_links = ('first_name', 'last_name')
```

In this example, the change list page grid will have no links:

```
class AuditEntryAdmin(admin.ModelAdmin):
    list_display = ('timestamp', 'message')
    list_display_links = None
```

#### `ModelAdmin.list_editable`

Set `list_editable` to a list of field names on the model which will allow editing on the change list page. That is, fields listed in `list_editable` will be displayed as form widgets on the change list page, allowing users to edit and save multiple rows at once.

---

**Note:** `list_editable` interacts with a couple of other options in particular ways; you should note the following rules:

- Any field in `list_editable` must also be in `list_display`. You can’t edit a field that’s not displayed!
- The same field can’t be listed in both `list_editable` and `list_display_links` – a field can’t be both a form and a link.

You’ll get a validation error if either of these rules are broken.

---

#### `ModelAdmin.list_filter`

Set `list_filter` to activate filters in the right sidebar of the change list page of the admin, as illustrated in the following screenshot:

Select user to change ADD USER +

Q

Action:   0 of 3 selected

<input type="checkbox"/>	USERNAME	EMAIL ADDRESS	FIRST NAME	LAST NAME	STAFF STATUS

<input type="checkbox"/>	simon	simon@example.com	Simon	Willison	<input type="radio"/>

3 users

**FILTER**

By staff status

All  
 Yes  
 No

By superuser status

All  
 Yes  
 No

By active

All  
 Yes  
 No

`list_filter` should be a list or tuple of elements, where each element should be of one of the following types:

- a field name, where the specified field should be either a `BooleanField`, `CharField`, `DateField`, `DateTimeField`, `IntegerField`, `ForeignKey` or `ManyToManyField`, for example:

```
class PersonAdmin(admin.ModelAdmin):
    list_filter = ('is_staff', 'company')
```

Field names in `list_filter` can also span relations using the `__` lookup, for example:

```
class PersonAdmin(admin.UserAdmin):
    list_filter = ('company__name',)
```

- a class inheriting from `django.contrib.admin.SimpleListFilter`, which you need to provide the `title` and `parameter_name` attributes to and override the `lookups` and `queryset` methods, e.g.:

```
from datetime import date

from django.contrib import admin
from django.utils.translation import ugettext_lazy as _

class DecadeBornListFilter(admin.SimpleListFilter):
    # Human-readable title which will be displayed in the
    # right admin sidebar just above the filter options.
    title = _('decade born')

    # Parameter for the filter that will be used in the URL query.
    parameter_name = 'decade'

    def lookups(self, request, model_admin):
        """
        Returns a list of tuples. The first element in each
        tuple is the coded value for the option that will
        appear in the URL query. The second element is the
        human-readable name for the option that will appear
        in the right sidebar.
        """
        return (
```

```
        ('80s', _('in the eighties')),
        ('90s', _('in the nineties')),
    )

    def queryset(self, request, queryset):
        """
        Returns the filtered queryset based on the value
        provided in the query string and retrievable via
        `self.value()`.
        """
        # Compare the requested value (either '80s' or '90s')
        # to decide how to filter the queryset.
        if self.value() == '80s':
            return queryset.filter(
                birthday__gte=date(1980, 1, 1),
                birthday__lte=date(1989, 12, 31))
        if self.value() == '90s':
            return queryset.filter(
                birthday__gte=date(1990, 1, 1),
                birthday__lte=date(1999, 12, 31))

class PersonAdmin(admin.ModelAdmin):
    list_filter = (DecadeBornListFilter,)
```

**Note:** As a convenience, the `HttpRequest` object is passed to the `lookups` and `queryset` methods, for example:

```
class AuthDecadeBornListFilter(DecadeBornListFilter):

    def lookups(self, request, model_admin):
        if request.user.is_superuser:
            return super(AuthDecadeBornListFilter, self).lookups(request,
↪model_admin)

    def queryset(self, request, queryset):
        if request.user.is_superuser:
            return super(AuthDecadeBornListFilter, self).queryset(request,
↪queryset)
```

Also as a convenience, the `ModelAdmin` object is passed to the `lookups` method, for example if you want to base the lookups on the available data:

```
class AdvancedDecadeBornListFilter(DecadeBornListFilter):

    def lookups(self, request, model_admin):
        """
        Only show the lookups if there actually is
        anyone born in the corresponding decades.
        """
        qs = model_admin.get_queryset(request)
        if qs.filter(birthday__gte=date(1980, 1, 1),
                    birthday__lte=date(1989, 12, 31)).exists():
            yield ('80s', _('in the eighties'))
        if qs.filter(birthday__gte=date(1990, 1, 1),
                    birthday__lte=date(1999, 12, 31)).exists():
            yield ('90s', _('in the nineties'))
```

- a tuple, where the first element is a field name and the second element is a class inheriting from `django`.

`contrib.admin.FieldListFilter`, for example:

```
class PersonAdmin(admin.ModelAdmin):
    list_filter = (
        ('is_staff', admin.BooleanFieldListFilter),
    )
```

You can limit the choices of a related model to the objects involved in that relation using `RelatedOnlyFieldListFilter`:

```
class BookAdmin(admin.ModelAdmin):
    list_filter = (
        ('author', admin.RelatedOnlyFieldListFilter),
    )
```

Assuming `author` is a `ForeignKey` to a `User` model, this will limit the `list_filter` choices to the users who have written a book instead of listing all users.

---

**Note:** The `FieldListFilter` API is considered internal and might be changed.

---

List filter's typically appear only if the filter has more than one choice. A filter's `has_output()` method controls whether or not it appears.

It is possible to specify a custom template for rendering a list filter:

```
class FilterWithCustomTemplate(admin.SimpleListFilter):
    template = "custom_template.html"
```

See the default template provided by Django (`admin/filter.html`) for a concrete example.

#### `ModelAdmin.list_max_show_all`

Set `list_max_show_all` to control how many items can appear on a “Show all” admin change list page. The admin will display a “Show all” link on the change list only if the total result count is less than or equal to this setting. By default, this is set to 200.

#### `ModelAdmin.list_per_page`

Set `list_per_page` to control how many items appear on each paginated admin change list page. By default, this is set to 100.

#### `ModelAdmin.list_select_related`

Set `list_select_related` to tell Django to use `select_related()` in retrieving the list of objects on the admin change list page. This can save you a bunch of database queries.

The value should be either a boolean, a list or a tuple. Default is `False`.

When value is `True`, `select_related()` will always be called. When value is set to `False`, Django will look at `list_display` and call `select_related()` if any `ForeignKey` is present.

If you need more fine-grained control, use a tuple (or list) as value for `list_select_related`. Empty tuple will prevent Django from calling `select_related` at all. Any other tuple will be passed directly to `select_related` as parameters. For example:

```
class ArticleAdmin(admin.ModelAdmin):
    list_select_related = ('author', 'category')
```

will call `select_related('author', 'category')`.

If you need to specify a dynamic value based on the request, you can implement a `get_list_select_related()` method.

**ModelAdmin.ordering**

Set `ordering` to specify how lists of objects should be ordered in the Django admin views. This should be a list or tuple in the same format as a model's `ordering` parameter.

If this isn't provided, the Django admin will use the model's default ordering.

If you need to specify a dynamic order (for example depending on user or language) you can implement a `get_ordering()` method.

**ModelAdmin.paginator**

The paginator class to be used for pagination. By default, `django.core.paginator.Paginator` is used. If the custom paginator class doesn't have the same constructor interface as `django.core.paginator.Paginator`, you will also need to provide an implementation for `ModelAdmin.get_paginator()`.

**ModelAdmin.prepopulated\_fields**

Set `prepopulated_fields` to a dictionary mapping field names to the fields it should prepopulate from:

```
class ArticleAdmin(admin.ModelAdmin):
    prepopulated_fields = {"slug": ("title",)}
```

When set, the given fields will use a bit of JavaScript to populate from the fields assigned. The main use for this functionality is to automatically generate the value for `SlugField` fields from one or more other fields. The generated value is produced by concatenating the values of the source fields, and then by transforming that result into a valid slug (e.g. substituting dashes for spaces).

`prepopulated_fields` doesn't accept `DateTimeField`, `ForeignKey`, nor `ManyToManyField` fields.

**ModelAdmin.preserve\_filters**

The admin now preserves filters on the list view after creating, editing or deleting an object. You can restore the previous behavior of clearing filters by setting this attribute to `False`.

**ModelAdmin.radio\_fields**

By default, Django's admin uses a select-box interface (`<select>`) for fields that are `ForeignKey` or have `choices` set. If a field is present in `radio_fields`, Django will use a radio-button interface instead. Assuming `group` is a `ForeignKey` on the `Person` model:

```
class PersonAdmin(admin.ModelAdmin):
    radio_fields = {"group": admin.VERTICAL}
```

You have the choice of using `HORIZONTAL` or `VERTICAL` from the `django.contrib.admin` module.

Don't include a field in `radio_fields` unless it's a `ForeignKey` or has `choices` set.

**ModelAdmin.raw\_id\_fields**

By default, Django's admin uses a select-box interface (`<select>`) for fields that are `ForeignKey`. Sometimes you don't want to incur the overhead of having to select all the related instances to display in the drop-down.

`raw_id_fields` is a list of fields you would like to change into an `Input` widget for either a `ForeignKey` or `ManyToManyField`:

```
class ArticleAdmin(admin.ModelAdmin):
    raw_id_fields = ("newspaper",)
```

The `raw_id_fields` `Input` widget should contain a primary key if the field is a `ForeignKey` or a comma separated list of values if the field is a `ManyToManyField`. The `raw_id_fields` widget shows a magnifying glass button next to the field which allows users to search for and select a value:

---

Newspaper:

---

**ModelAdmin.readonly\_fields**

By default the admin shows all fields as editable. Any fields in this option (which should be a list or tuple) will display its data as-is and non-editable; they are also excluded from the *ModelForm* used for creating and editing. Note that when specifying *ModelAdmin.fields* or *ModelAdmin.fieldsets* the read-only fields must be present to be shown (they are ignored otherwise).

If *readonly\_fields* is used without defining explicit ordering through *ModelAdmin.fields* or *ModelAdmin.fieldsets* they will be added last after all editable fields.

A read-only field can not only display data from a model's field, it can also display the output of a model's method or a method of the *ModelAdmin* class itself. This is very similar to the way *ModelAdmin.list\_display* behaves. This provides an easy way to use the admin interface to provide feedback on the status of the objects being edited, for example:

```
from django.contrib import admin
from django.utils.html import format_html_join
from django.utils.safestring import mark_safe

class PersonAdmin(admin.ModelAdmin):
    readonly_fields = ('address_report',)

    def address_report(self, instance):
        # assuming get_full_address() returns a list of strings
        # for each line of the address and you want to separate each
        # line by a linebreak
        return format_html_join(
            mark_safe('<br/>'),
            '{}',
            ((line,) for line in instance.get_full_address()),
        ) or mark_safe("<span class='errors'>I can't determine this address.</span>")

    # short_description functions like a model field's verbose_name
    address_report.short_description = "Address"
```

**ModelAdmin.save\_as**

Set *save\_as* to enable a “save as new” feature on admin change forms.

Normally, objects have three save options: “Save”, “Save and continue editing”, and “Save and add another”. If *save\_as* is *True*, “Save and add another” will be replaced by a “Save as new” button that creates a new object (with a new ID) rather than updating the existing object.

By default, *save\_as* is set to *False*.

**ModelAdmin.save\_as\_continue**

When *save\_as=True*, the default redirect after saving the new object is to the change view for that object. If you set *save\_as\_continue=False*, the redirect will be to the changelist view.

By default, *save\_as\_continue* is set to *True*.

**ModelAdmin.save\_on\_top**

Set *save\_on\_top* to add save buttons across the top of your admin change forms.

Normally, the save buttons appear only at the bottom of the forms. If you set `save_on_top`, the buttons will appear both on the top and the bottom.

By default, `save_on_top` is set to `False`.

#### ModelAdmin.`search_fields`

Set `search_fields` to enable a search box on the admin change list page. This should be set to a list of field names that will be searched whenever somebody submits a search query in that text box.

These fields should be some kind of text field, such as `CharField` or `TextField`. You can also perform a related lookup on a `ForeignKey` or `ManyToManyField` with the lookup API “follow” notation:

```
search_fields = ['foreign_key__related_fieldname']
```

For example, if you have a blog entry with an author, the following definition would enable searching blog entries by the email address of the author:

```
search_fields = ['user__email']
```

When somebody does a search in the admin search box, Django splits the search query into words and returns all objects that contain each of the words, case insensitive, where each word must be in at least one of `search_fields`. For example, if `search_fields` is set to `['first_name', 'last_name']` and a user searches for `john lennon`, Django will do the equivalent of this SQL WHERE clause:

```
WHERE (first_name ILIKE '%john%' OR last_name ILIKE '%john%')
AND (first_name ILIKE '%lennon%' OR last_name ILIKE '%lennon%')
```

For faster and/or more restrictive searches, prefix the field name with an operator:

- ^ Use the ‘^’ operator to match starting at the beginning of the field. For example, if `search_fields` is set to `['^first_name', '^last_name']` and a user searches for `john lennon`, Django will do the equivalent of this SQL WHERE clause:

```
WHERE (first_name ILIKE 'john%' OR last_name ILIKE 'john%')
AND (first_name ILIKE 'lennon%' OR last_name ILIKE 'lennon%')
```

This query is more efficient than the normal `'%john%'` query, because the database only needs to check the beginning of a column’s data, rather than seeking through the entire column’s data. Plus, if the column has an index on it, some databases may be able to use the index for this query, even though it’s a LIKE query.

- = Use the ‘=’ operator for case-insensitive exact matching. For example, if `search_fields` is set to `['=first_name', '=last_name']` and a user searches for `john lennon`, Django will do the equivalent of this SQL WHERE clause:

```
WHERE (first_name ILIKE 'john' OR last_name ILIKE 'john')
AND (first_name ILIKE 'lennon' OR last_name ILIKE 'lennon')
```

Note that the query input is split by spaces, so, following this example, it’s currently not possible to search for all records in which `first_name` is exactly `'john winston'` (containing a space).

- @ Using the ‘@’ operator to perform a full text match. This is like the default search method but uses an index. Currently this is only available for MySQL.

If you need to customize search you can use `ModelAdmin.get_search_results()` to provide additional or alternate search behavior.

#### ModelAdmin.`show_full_result_count`

Set `show_full_result_count` to control whether the full count of objects should be displayed on a filtered

admin page (e.g. 99 results (103 total)). If this option is set to `False`, a text like 99 results (Show all) is displayed instead.

The default of `show_full_result_count=True` generates a query to perform a full count on the table which can be expensive if the table contains a large number of rows.

#### `ModelAdmin.view_on_site`

Set `view_on_site` to control whether or not to display the “View on site” link. This link should bring you to a URL where you can display the saved object.

This value can be either a boolean flag or a callable. If `True` (the default), the object’s `get_absolute_url()` method will be used to generate the url.

If your model has a `get_absolute_url()` method but you don’t want the “View on site” button to appear, you only need to set `view_on_site` to `False`:

```
from django.contrib import admin

class PersonAdmin(admin.ModelAdmin):
    view_on_site = False
```

In case it is a callable, it accepts the model instance as a parameter. For example:

```
from django.contrib import admin
from django.urls import reverse

class PersonAdmin(admin.ModelAdmin):
    def view_on_site(self, obj):
        url = reverse('person-detail', kwargs={'slug': obj.slug})
        return 'https://example.com' + url
```

## Custom template options

The *Overriding admin templates* section describes how to override or extend the default admin templates. Use the following options to override the default templates used by the `ModelAdmin` views:

#### `ModelAdmin.add_form_template`

Path to a custom template, used by `add_view()`.

#### `ModelAdmin.change_form_template`

Path to a custom template, used by `change_view()`.

#### `ModelAdmin.change_list_template`

Path to a custom template, used by `changelist_view()`.

#### `ModelAdmin.delete_confirmation_template`

Path to a custom template, used by `delete_view()` for displaying a confirmation page when deleting one or more objects.

#### `ModelAdmin.delete_selected_confirmation_template`

Path to a custom template, used by the `delete_selected` action method for displaying a confirmation page when deleting one or more objects. See the *actions documentation*.

#### `ModelAdmin.object_history_template`

Path to a custom template, used by `history_view()`.

## ModelAdmin methods

**Warning:** When overriding `ModelAdmin.save_model()` and `ModelAdmin.delete_model()`, your code must save/delete the object. They aren't meant for veto purposes, rather they allow you to perform extra operations.

`ModelAdmin.save_model(request, obj, form, change)`

The `save_model` method is given the `HttpRequest`, a model instance, a `ModelForm` instance, and a boolean value based on whether it is adding or changing the object. Overriding this method allows doing pre- or post-save operations. Call `super().save_model()` to save the object using `Model.save()`.

For example to attach `request.user` to the object prior to saving:

```
from django.contrib import admin

class ArticleAdmin(admin.ModelAdmin):
    def save_model(self, request, obj, form, change):
        obj.user = request.user
        super(ArticleAdmin, self).save_model(request, obj, form, change)
```

`ModelAdmin.delete_model(request, obj)`

The `delete_model` method is given the `HttpRequest` and a model instance. Overriding this method allows doing pre- or post-delete operations. Call `super().delete_model()` to delete the object using `Model.delete()`.

`ModelAdmin.save_formset(request, form, formset, change)`

The `save_formset` method is given the `HttpRequest`, the parent `ModelForm` instance and a boolean value based on whether it is adding or changing the parent object.

For example, to attach `request.user` to each changed formset model instance:

```
class ArticleAdmin(admin.ModelAdmin):
    def save_formset(self, request, form, formset, change):
        instances = formset.save(commit=False)
        for obj in formset.deleted_objects:
            obj.delete()
        for instance in instances:
            instance.user = request.user
            instance.save()
        formset.save_m2m()
```

See also *Saving objects in the formset*.

`ModelAdmin.get_ordering(request)`

The `get_ordering` method takes a `request` as parameter and is expected to return a list or tuple for ordering similar to the `ordering` attribute. For example:

```
class PersonAdmin(admin.ModelAdmin):

    def get_ordering(self, request):
        if request.user.is_superuser:
            return ['name', 'rank']
        else:
            return ['name']
```

`ModelAdmin.get_search_results(request, queryset, search_term)`

The `get_search_results` method modifies the list of objects displayed into those that match the provided search term. It accepts the request, a queryset that applies the current filters, and the user-provided search term. It returns a tuple containing a queryset modified to implement the search, and a boolean indicating if the results may contain duplicates.

The default implementation searches the fields named in `ModelAdmin.search_fields`.

This method may be overridden with your own custom search method. For example, you might wish to search by an integer field, or use an external tool such as Solr or Haystack. You must establish if the queryset changes implemented by your search method may introduce duplicates into the results, and return `True` in the second element of the return value.

For example, to search by name and age, you could use:

```
class PersonAdmin(admin.ModelAdmin):
    list_display = ('name', 'age')
    search_fields = ('name',)

    def get_search_results(self, request, queryset, search_term):
        queryset, use_distinct = super(PersonAdmin, self).get_search_
        ↪results(request, queryset, search_term)
        try:
            search_term_as_int = int(search_term)
        except ValueError:
            pass
        else:
            queryset |= self.model.objects.filter(age=search_term_as_int)
        return queryset, use_distinct
```

This implementation is more efficient than `search_fields = ('name', '=age')` which results in a string comparison for the numeric field, for example `... OR UPPER("polls_choice"."votes")::text) = UPPER('4')` on PostgreSQL.

`ModelAdmin.save_related` (*request, form, formsets, change*)

The `save_related` method is given the `HttpRequest`, the parent `ModelForm` instance, the list of inline formsets and a boolean value based on whether the parent is being added or changed. Here you can do any pre- or post-save operations for objects related to the parent. Note that at this point the parent object and its form have already been saved.

`ModelAdmin.get_readonly_fields` (*request, obj=None*)

The `get_readonly_fields` method is given the `HttpRequest` and the `obj` being edited (or `None` on an add form) and is expected to return a list or tuple of field names that will be displayed as read-only, as described above in the `ModelAdmin.readonly_fields` section.

`ModelAdmin.get_prepopulated_fields` (*request, obj=None*)

The `get_prepopulated_fields` method is given the `HttpRequest` and the `obj` being edited (or `None` on an add form) and is expected to return a dictionary, as described above in the `ModelAdmin.prepopulated_fields` section.

`ModelAdmin.get_list_display` (*request*)

The `get_list_display` method is given the `HttpRequest` and is expected to return a list or tuple of field names that will be displayed on the changelist view as described above in the `ModelAdmin.list_display` section.

`ModelAdmin.get_list_display_links` (*request, list\_display*)

The `get_list_display_links` method is given the `HttpRequest` and the list or tuple returned by `ModelAdmin.get_list_display()`. It is expected to return either `None` or a list or tuple of field names on the changelist that will be linked to the change view, as described in the `ModelAdmin.list_display_links` section.

`ModelAdmin.get_fields` (*request*, *obj=None*)

The `get_fields` method is given the `HttpRequest` and the `obj` being edited (or `None` on an add form) and is expected to return a list of fields, as described above in the `ModelAdmin.fields` section.

`ModelAdmin.get_fieldsets` (*request*, *obj=None*)

The `get_fieldsets` method is given the `HttpRequest` and the `obj` being edited (or `None` on an add form) and is expected to return a list of two-tuples, in which each two-tuple represents a `<fieldset>` on the admin form page, as described above in the `ModelAdmin.fieldsets` section.

`ModelAdmin.get_list_filter` (*request*)

The `get_list_filter` method is given the `HttpRequest` and is expected to return the same kind of sequence type as for the `list_filter` attribute.

`ModelAdmin.get_list_select_related` (*request*)

The `get_list_select_related` method is given the `HttpRequest` and should return a boolean or list as `ModelAdmin.list_select_related` does.

`ModelAdmin.get_search_fields` (*request*)

The `get_search_fields` method is given the `HttpRequest` and is expected to return the same kind of sequence type as for the `search_fields` attribute.

`ModelAdmin.get_inline_instances` (*request*, *obj=None*)

The `get_inline_instances` method is given the `HttpRequest` and the `obj` being edited (or `None` on an add form) and is expected to return a list or tuple of `InlineModelAdmin` objects, as described below in the `InlineModelAdmin` section. For example, the following would return inlines without the default filtering based on add, change, and delete permissions:

```
class MyModelAdmin(admin.ModelAdmin):
    inlines = (MyInline,)

    def get_inline_instances(self, request, obj=None):
        return [inline(self.model, self.admin_site) for inline in self.inlines]
```

If you override this method, make sure that the returned inlines are instances of the classes defined in `inlines` or you might encounter a “Bad Request” error when adding related objects.

`ModelAdmin.get_urls` ()

The `get_urls` method on a `ModelAdmin` returns the URLs to be used for that `ModelAdmin` in the same way as a `URLconf`. Therefore you can extend them as documented in `URL dispatcher`:

```
class MyModelAdmin(admin.ModelAdmin):
    def get_urls(self):
        urls = super(MyModelAdmin, self).get_urls()
        my_urls = [
            url(r'^my_view/$', self.my_view),
        ]
        return my_urls + urls

    def my_view(self, request):
        # ...
        context = dict(
            # Include common variables for rendering the admin template.
            self.admin_site.each_context(request),
            # Anything else you want in the context...
            key=value,
        )
        return TemplateResponse(request, "somemplate.html", context)
```

If you want to use the admin layout, extend from `admin/base_site.html`:

```
{% extends "admin/base_site.html" %}
{% block content %}
...
{% endblock %}
```

**Note:** Notice that the custom patterns are included *before* the regular admin URLs: the admin URL patterns are very permissive and will match nearly anything, so you'll usually want to prepend your custom URLs to the built-in ones.

In this example, `my_view` will be accessed at `/admin/myapp/mymodel/my_view/` (assuming the admin URLs are included at `/admin/.`)

However, the `self.my_view` function registered above suffers from two problems:

- It will *not* perform any permission checks, so it will be accessible to the general public.
- It will *not* provide any header details to prevent caching. This means if the page retrieves data from the database, and caching middleware is active, the page could show outdated information.

Since this is usually not what you want, Django provides a convenience wrapper to check permissions and mark the view as non-cacheable. This wrapper is `AdminSite.admin_view()` (i.e. `self.admin_site.admin_view` inside a `ModelAdmin` instance); use it like so:

```
class MyModelAdmin(admin.ModelAdmin):
    def get_urls(self):
        urls = super(MyModelAdmin, self).get_urls()
        my_urls = [
            url(r'^my_view/$', self.admin_site.admin_view(self.my_view))
        ]
        return my_urls + urls
```

Notice the wrapped view in the fifth line above:

```
url(r'^my_view/$', self.admin_site.admin_view(self.my_view))
```

This wrapping will protect `self.my_view` from unauthorized access and will apply the `django.views.decorators.cache.never_cache()` decorator to make sure it is not cached if the cache middleware is active.

If the page is cacheable, but you still want the permission check to be performed, you can pass a `cacheable=True` argument to `AdminSite.admin_view()`:

```
url(r'^my_view/$', self.admin_site.admin_view(self.my_view, cacheable=True))
```

`ModelAdmin` views have `model_admin` attributes. Other `AdminSite` views have `admin_site` attributes.

`ModelAdmin.get_form(request, obj=None, **kwargs)`

Returns a `ModelForm` class for use in the admin add and change views, see `add_view()` and `change_view()`.

The base implementation uses `model_form_factory()` to subclass `form`, modified by attributes such as `fields` and `exclude`. So, for example, if you wanted to offer additional fields to superusers, you could swap in a different base form like so:

```
class MyModelAdmin(admin.ModelAdmin):
    def get_form(self, request, obj=None, **kwargs):
```

```

if request.user.is_superuser:
    kwargs['form'] = MySuperuserForm
return super(MyModelAdmin, self).get_form(request, obj, **kwargs)

```

You may also simply return a custom *ModelForm* class directly.

`ModelAdmin.get_formsets_with_inlines` (*request*, *obj=None*)

Yields (*FormSet*, *InlineModelAdmin*) pairs for use in admin add and change views.

For example if you wanted to display a particular inline only in the change view, you could override `get_formsets_with_inlines` as follows:

```

class MyModelAdmin(admin.ModelAdmin):
    inlines = [MyInline, SomeOtherInline]

    def get_formsets_with_inlines(self, request, obj=None):
        for inline in self.get_inline_instances(request, obj):
            # hide MyInline in the add view
            if isinstance(inline, MyInline) and obj is None:
                continue
            yield inline.get_formset(request, obj), inline

```

`ModelAdmin.formfield_for_foreignkey` (*db\_field*, *request*, *\*\*kwargs*)

The `formfield_for_foreignkey` method on a `ModelAdmin` allows you to override the default formfield for a foreign keys field. For example, to return a subset of objects for this foreign key field based on the user:

```

class MyModelAdmin(admin.ModelAdmin):
    def formfield_for_foreignkey(self, db_field, request, **kwargs):
        if db_field.name == "car":
            kwargs["queryset"] = Car.objects.filter(owner=request.user)
        return super(MyModelAdmin, self).formfield_for_foreignkey(db_field,
↳request, **kwargs)

```

This uses the `HttpRequest` instance to filter the `Car` foreign key field to only display the cars owned by the `User` instance.

`ModelAdmin.formfield_for_manytomany` (*db\_field*, *request*, *\*\*kwargs*)

Like the `formfield_for_foreignkey` method, the `formfield_for_manytomany` method can be overridden to change the default formfield for a many to many field. For example, if an owner can own multiple cars and cars can belong to multiple owners – a many to many relationship – you could filter the `Car` foreign key field to only display the cars owned by the `User`:

```

class MyModelAdmin(admin.ModelAdmin):
    def formfield_for_manytomany(self, db_field, request, **kwargs):
        if db_field.name == "cars":
            kwargs["queryset"] = Car.objects.filter(owner=request.user)
        return super(MyModelAdmin, self).formfield_for_manytomany(db_field,
↳request, **kwargs)

```

`ModelAdmin.formfield_for_choice_field` (*db\_field*, *request*, *\*\*kwargs*)

Like the `formfield_for_foreignkey` and `formfield_for_manytomany` methods, the `formfield_for_choice_field` method can be overridden to change the default formfield for a field that has declared choices. For example, if the choices available to a superuser should be different than those available to regular staff, you could proceed as follows:

```

class MyModelAdmin(admin.ModelAdmin):
    def formfield_for_choice_field(self, db_field, request, **kwargs):

```

```

    if db_field.name == "status":
        kwargs['choices'] = (
            ('accepted', 'Accepted'),
            ('denied', 'Denied'),
        )
        if request.user.is_superuser:
            kwargs['choices'] += (('ready', 'Ready for deployment'),)
    return super(MyModelAdmin, self).formfield_for_choice_field(db_field,
↳request, **kwargs)

```

**Note**

Any choices attribute set on the formfield will be limited to the form field only. If the corresponding field on the model has choices set, the choices provided to the form must be a valid subset of those choices, otherwise the form submission will fail with a *ValidationError* when the model itself is validated before saving.

`ModelAdmin.get_changelist` (*request*, *\*\*kwargs*)

Returns the *Changelist* class to be used for listing. By default, `django.contrib.admin.views.main.ChangeList` is used. By inheriting this class you can change the behavior of the listing.

`ModelAdmin.get_changelist_form` (*request*, *\*\*kwargs*)

Returns a *ModelForm* class for use in the *Formset* on the changelist page. To use a custom form, for example:

```

from django import forms

class MyForm(forms.ModelForm):
    pass

class MyModelAdmin(admin.ModelAdmin):
    def get_changelist_form(self, request, **kwargs):
        return MyForm

```

**Note**

If you define the `Meta.model` attribute on a *ModelForm*, you must also define the `Meta.fields` attribute (or the `Meta.exclude` attribute). However, *ModelAdmin* ignores this value, overriding it with the `ModelAdmin.list_editable` attribute. The easiest solution is to omit the `Meta.model` attribute, since *ModelAdmin* will provide the correct model to use.

`ModelAdmin.get_changelist_formset` (*request*, *\*\*kwargs*)

Returns a *ModelFormSet* class for use on the changelist page if `list_editable` is used. To use a custom formset, for example:

```

from django.forms import BaseModelFormSet

class MyAdminFormSet(BaseModelFormSet):
    pass

class MyModelAdmin(admin.ModelAdmin):
    def get_changelist_formset(self, request, **kwargs):
        kwargs['formset'] = MyAdminFormSet
        return super(MyModelAdmin, self).get_changelist_formset(request, **kwargs)

```

`ModelAdmin.has_add_permission(request)`

Should return `True` if adding an object is permitted, `False` otherwise.

`ModelAdmin.has_change_permission(request, obj=None)`

Should return `True` if editing `obj` is permitted, `False` otherwise. If `obj` is `None`, should return `True` or `False` to indicate whether editing of objects of this type is permitted in general (e.g., `False` will be interpreted as meaning that the current user is not permitted to edit any object of this type).

`ModelAdmin.has_delete_permission(request, obj=None)`

Should return `True` if deleting `obj` is permitted, `False` otherwise. If `obj` is `None`, should return `True` or `False` to indicate whether deleting objects of this type is permitted in general (e.g., `False` will be interpreted as meaning that the current user is not permitted to delete any object of this type).

`ModelAdmin.has_module_permission(request)`

Should return `True` if displaying the module on the admin index page and accessing the module's index page is permitted, `False` otherwise. Uses `User.has_module_perms()` by default. Overriding it does not restrict access to the add, change or delete views, `has_add_permission()`, `has_change_permission()`, and `has_delete_permission()` should be used for that.

`ModelAdmin.get_queryset(request)`

The `get_queryset` method on a `ModelAdmin` returns a `QuerySet` of all model instances that can be edited by the admin site. One use case for overriding this method is to show objects owned by the logged-in user:

```
class MyModelAdmin(admin.ModelAdmin):
    def get_queryset(self, request):
        qs = super(MyModelAdmin, self).get_queryset(request)
        if request.user.is_superuser:
            return qs
        return qs.filter(author=request.user)
```

`ModelAdmin.message_user(request, message, level=messages.INFO, extra_tags='', fail_silently=False)`

Sends a message to the user using the `django.contrib.messages` backend. See the [custom ModelAdmin example](#).

Keyword arguments allow you to change the message level, add extra CSS tags, or fail silently if the `contrib.messages` framework is not installed. These keyword arguments match those for `django.contrib.messages.add_message()`, see that function's documentation for more details. One difference is that the level may be passed as a string label in addition to integer/constant.

`ModelAdmin.get_paginator(request, queryset, per_page, orphans=0, allow_empty_first_page=True)`

Returns an instance of the paginator to use for this view. By default, instantiates an instance of `paginator`.

`ModelAdmin.response_add(request, obj, post_url_continue=None)`

Determines the `HttpResponse` for the `add_view()` stage.

`response_add` is called after the admin form is submitted and just after the object and all the related instances have been created and saved. You can override it to change the default behavior after the object has been created.

`ModelAdmin.response_change(request, obj)`

Determines the `HttpResponse` for the `change_view()` stage.

`response_change` is called after the admin form is submitted and just after the object and all the related instances have been saved. You can override it to change the default behavior after the object has been changed.

`ModelAdmin.response_delete(request, obj_display, obj_id)`

Determines the `HttpResponse` for the `delete_view()` stage.

`response_delete` is called after the object has been deleted. You can override it to change the default behavior after the object has been deleted.

`obj_display` is a string with the name of the deleted object.

`obj_id` is the serialized identifier used to retrieve the object to be deleted.

`ModelAdmin.get_changeform_initial_data` (*request*)

A hook for the initial data on admin change forms. By default, fields are given initial values from GET parameters. For instance, `?name=initial_value` will set the `name` field's initial value to be `initial_value`.

This method should return a dictionary in the form `{'fieldname': 'fieldval'}`:

```
def get_changeform_initial_data(self, request):
    return {'name': 'custom_initial_value'}
```

## Other methods

`ModelAdmin.add_view` (*request*, *form\_url*='', *extra\_context*=None)

Django view for the model instance addition page. See note below.

`ModelAdmin.change_view` (*request*, *object\_id*, *form\_url*='', *extra\_context*=None)

Django view for the model instance editing page. See note below.

`ModelAdmin.changelist_view` (*request*, *extra\_context*=None)

Django view for the model instances change list/actions page. See note below.

`ModelAdmin.delete_view` (*request*, *object\_id*, *extra\_context*=None)

Django view for the model instance(s) deletion confirmation page. See note below.

`ModelAdmin.history_view` (*request*, *object\_id*, *extra\_context*=None)

Django view for the page that shows the modification history for a given model instance.

Unlike the hook-type `ModelAdmin` methods detailed in the previous section, these five methods are in reality designed to be invoked as Django views from the admin application URL dispatching handler to render the pages that deal with model instances CRUD operations. As a result, completely overriding these methods will significantly change the behavior of the admin application.

One common reason for overriding these methods is to augment the context data that is provided to the template that renders the view. In the following example, the `change_view` is overridden so that the rendered template is provided some extra mapping data that would not otherwise be available:

```
class MyModelAdmin(admin.ModelAdmin):

    # A template for a very customized change view:
    change_form_template = 'admin/myapp/extras/openstreetmap_change_form.html'

    def get_osm_info(self):
        # ...
        pass

    def change_view(self, request, object_id, form_url='', extra_context=None):
        extra_context = extra_context or {}
        extra_context['osm_data'] = self.get_osm_info()
        return super(MyModelAdmin, self).change_view(
            request, object_id, form_url, extra_context=extra_context,
        )
```

These views return `TemplateResponse` instances which allow you to easily customize the response data before rendering. For more details, see the [TemplateResponse documentation](#).

## ModelAdmin asset definitions

There are times where you would like add a bit of CSS and/or JavaScript to the add/change views. This can be accomplished by using a `Media` inner class on your `ModelAdmin`:

```
class ArticleAdmin(admin.ModelAdmin):
    class Media:
        css = {
            "all": ("my_styles.css",)
        }
        js = ("my_code.js",)
```

The `staticfiles` app prepends `STATIC_URL` (or `MEDIA_URL` if `STATIC_URL` is `None`) to any asset paths. The same rules apply as *regular asset definitions on forms*.

## jQuery

Django admin JavaScript makes use of the jQuery library.

To avoid conflicts with user-supplied scripts or libraries, Django's jQuery (version 2.2.3) is namespaced as `django.jQuery`. If you want to use jQuery in your own admin JavaScript without including a second copy, you can use the `django.jQuery` object on `changelist` and `add/edit` views.

The embedded jQuery was upgraded from 1.11.2 to 2.1.4. This drops support for Internet Explorer 8 and below. You can restore support by *including your own version of jQuery 1.X*.

The embedded jQuery was upgraded from 2.1.4 to 2.2.3.

The `ModelAdmin` class requires jQuery by default, so there is no need to add jQuery to your `ModelAdmin`'s list of media resources unless you have a specific need. For example, if you require the jQuery library to be in the global namespace (for example when using third-party jQuery plugins) or if you need a newer version of jQuery, you will have to include your own copy.

Django provides both uncompressed and 'minified' versions of jQuery, as `jquery.js` and `jquery.min.js` respectively.

`ModelAdmin` and `InlineModelAdmin` have a `media` property that returns a list of `Media` objects which store paths to the JavaScript files for the forms and/or formsets. If `DEBUG` is `True` it will return the uncompressed versions of the various JavaScript files, including `jquery.js`; if not, it will return the 'minified' versions.

## Adding custom validation to the admin

Adding custom validation of data in the admin is quite easy. The automatic admin interface reuses `django.forms`, and the `ModelAdmin` class gives you the ability define your own form:

```
class ArticleAdmin(admin.ModelAdmin):
    form = MyArticleAdminForm
```

`MyArticleAdminForm` can be defined anywhere as long as you import where needed. Now within your form you can add your own custom validation for any field:

```
class MyArticleAdminForm(forms.ModelForm):
    def clean_name(self):
        # do something that validates your data
        return self.cleaned_data["name"]
```

It is important you use a `ModelForm` here otherwise things can break. See the *forms* documentation on *custom validation* and, more specifically, the *model form validation notes* for more information.

### InlineModelAdmin objects

**class** `InlineModelAdmin`

**class** `TabularInline`

**class** `StackedInline`

The admin interface has the ability to edit models on the same page as a parent model. These are called inlines. Suppose you have these two models:

```
from django.db import models

class Author(models.Model):
    name = models.CharField(max_length=100)

class Book(models.Model):
    author = models.ForeignKey(Author, on_delete=models.CASCADE)
    title = models.CharField(max_length=100)
```

You can edit the books authored by an author on the author page. You add inlines to a model by specifying them in a `ModelAdmin.inlines`:

```
from django.contrib import admin

class BookInline(admin.TabularInline):
    model = Book

class AuthorAdmin(admin.ModelAdmin):
    inlines = [
        BookInline,
    ]
```

Django provides two subclasses of `InlineModelAdmin` and they are:

- *TabularInline*
- *StackedInline*

The difference between these two is merely the template used to render them.

### InlineModelAdmin options

`InlineModelAdmin` shares many of the same features as `ModelAdmin`, and adds some of its own (the shared features are actually defined in the `BaseModelAdmin` superclass). The shared features are:

- *form*
- *fieldsets*
- *fields*
- *formfield\_overrides*
- *exclude*
- *filter\_horizontal*

- `filter_vertical`
- `ordering`
- `prepopulated_fields`
- `get_queryset()`
- `radio_fields`
- `readonly_fields`
- `raw_id_fields`
- `formfield_for_choice_field()`
- `formfield_for_foreignkey()`
- `formfield_for_manytomany()`
- `has_add_permission()`
- `has_change_permission()`
- `has_delete_permission()`
- `has_module_permission()`

The `InlineModelAdmin` class adds:

`InlineModelAdmin.model`

The model which the inline is using. This is required.

`InlineModelAdmin.fk_name`

The name of the foreign key on the model. In most cases this will be dealt with automatically, but `fk_name` must be specified explicitly if there are more than one foreign key to the same parent model.

`InlineModelAdmin.formset`

This defaults to `BaseInlineFormSet`. Using your own formset can give you many possibilities of customization. Inlines are built around *model formsets*.

`InlineModelAdmin.form`

The value for `form` defaults to `ModelForm`. This is what is passed through to `inlineformset_factory()` when creating the formset for this inline.

**Warning:** When writing custom validation for `InlineModelAdmin` forms, be cautious of writing validation that relies on features of the parent model. If the parent model fails to validate, it may be left in an inconsistent state as described in the warning in *Validation on a ModelForm*.

`InlineModelAdmin.classes`

A list or tuple containing extra CSS classes to apply to the fieldset that is rendered for the inlines. Defaults to `None`. As with classes configured in *fieldsets*, inlines with a `collapse` class will be initially collapsed and their header will have a small “show” link.

`InlineModelAdmin.extra`

This controls the number of extra forms the formset will display in addition to the initial forms. See the *formsets documentation* for more information.

For users with JavaScript-enabled browsers, an “Add another” link is provided to enable any number of additional inlines to be added in addition to those provided as a result of the `extra` argument.

The dynamic link will not appear if the number of currently displayed forms exceeds `max_num`, or if the user does not have JavaScript enabled.

`InlineModelAdmin.get_extra()` also allows you to customize the number of extra forms.

#### `InlineModelAdmin.max_num`

This controls the maximum number of forms to show in the inline. This doesn't directly correlate to the number of objects, but can if the value is small enough. See *Limiting the number of editable objects* for more information.

`InlineModelAdmin.get_max_num()` also allows you to customize the maximum number of extra forms.

#### `InlineModelAdmin.min_num`

This controls the minimum number of forms to show in the inline. See `modelformset_factory()` for more information.

`InlineModelAdmin.get_min_num()` also allows you to customize the minimum number of displayed forms.

#### `InlineModelAdmin.raw_id_fields`

By default, Django's admin uses a select-box interface (<select>) for fields that are `ForeignKey`. Sometimes you don't want to incur the overhead of having to select all the related instances to display in the drop-down.

`raw_id_fields` is a list of fields you would like to change into an `Input` widget for either a `ForeignKey` or `ManyToManyField`:

```
class BookInline(admin.TabularInline):
    model = Book
    raw_id_fields = ("pages",)
```

#### `InlineModelAdmin.template`

The template used to render the inline on the page.

#### `InlineModelAdmin.verbose_name`

An override to the `verbose_name` found in the model's inner `Meta` class.

#### `InlineModelAdmin.verbose_name_plural`

An override to the `verbose_name_plural` found in the model's inner `Meta` class.

#### `InlineModelAdmin.can_delete`

Specifies whether or not inline objects can be deleted in the inline. Defaults to `True`.

#### `InlineModelAdmin.show_change_link`

Specifies whether or not inline objects that can be changed in the admin have a link to the change form. Defaults to `False`.

#### `InlineModelAdmin.get_formset(request, obj=None, **kwargs)`

Returns a `BaseInlineFormSet` class for use in admin add/change views. See the example for `ModelAdmin.get_formsets_with_inlines`.

#### `InlineModelAdmin.get_extra(request, obj=None, **kwargs)`

Returns the number of extra inline forms to use. By default, returns the `InlineModelAdmin.extra` attribute.

Override this method to programmatically determine the number of extra inline forms. For example, this may be based on the model instance (passed as the keyword argument `obj`):

```
class BinaryTreeAdmin(admin.TabularInline):
    model = BinaryTree

    def get_extra(self, request, obj=None, **kwargs):
        extra = 2
        if obj:
            return extra - obj.binarytree_set.count()
        return extra
```

`InlineModelAdmin.get_max_num(request, obj=None, **kwargs)`

Returns the maximum number of extra inline forms to use. By default, returns the `InlineModelAdmin.max_num` attribute.

Override this method to programmatically determine the maximum number of inline forms. For example, this may be based on the model instance (passed as the keyword argument `obj`):

```
class BinaryTreeAdmin(admin.TabularInline):
    model = BinaryTree

    def get_max_num(self, request, obj=None, **kwargs):
        max_num = 10
        if obj and obj.parent:
            return max_num - 5
        return max_num
```

`InlineModelAdmin.get_min_num(request, obj=None, **kwargs)`

Returns the minimum number of inline forms to use. By default, returns the `InlineModelAdmin.min_num` attribute.

Override this method to programmatically determine the minimum number of inline forms. For example, this may be based on the model instance (passed as the keyword argument `obj`).

## Working with a model with two or more foreign keys to the same parent model

It is sometimes possible to have more than one foreign key to the same model. Take this model for instance:

```
from django.db import models

class Friendship(models.Model):
    to_person = models.ForeignKey(Person, on_delete=models.CASCADE, related_name=
↪ "friends")
    from_person = models.ForeignKey(Person, on_delete=models.CASCADE, related_name=
↪ "from_friends")
```

If you wanted to display an inline on the `Person` admin add/change pages you need to explicitly define the foreign key since it is unable to do so automatically:

```
from django.contrib import admin
from myapp.models import Friendship

class FriendshipInline(admin.TabularInline):
    model = Friendship
    fk_name = "to_person"

class PersonAdmin(admin.ModelAdmin):
    inlines = [
        FriendshipInline,
    ]
```

## Working with many-to-many models

By default, admin widgets for many-to-many relations will be displayed on whichever model contains the actual reference to the `ManyToManyField`. Depending on your `ModelAdmin` definition, each many-to-many field in

your model will be represented by a standard HTML `<select multiple>`, a horizontal or vertical filter, or a `raw_id_admin` widget. However, it is also possible to replace these widgets with inlines.

Suppose we have the following models:

```
from django.db import models

class Person(models.Model):
    name = models.CharField(max_length=128)

class Group(models.Model):
    name = models.CharField(max_length=128)
    members = models.ManyToManyField(Person, related_name='groups')
```

If you want to display many-to-many relations using an inline, you can do so by defining an `InlineModelAdmin` object for the relationship:

```
from django.contrib import admin

class MembershipInline(admin.TabularInline):
    model = Group.members.through

class PersonAdmin(admin.ModelAdmin):
    inlines = [
        MembershipInline,
    ]

class GroupAdmin(admin.ModelAdmin):
    inlines = [
        MembershipInline,
    ]
    exclude = ('members',)
```

There are two features worth noting in this example.

Firstly - the `MembershipInline` class references `Group.members.through`. The `through` attribute is a reference to the model that manages the many-to-many relation. This model is automatically created by Django when you define a many-to-many field.

Secondly, the `GroupAdmin` must manually exclude the `members` field. Django displays an admin widget for a many-to-many field on the model that defines the relation (in this case, `Group`). If you want to use an inline model to represent the many-to-many relationship, you must tell Django's admin to *not* display this widget - otherwise you will end up with two widgets on your admin page for managing the relation.

Note that when using this technique the `m2m_changed` signals aren't triggered. This is because as far as the admin is concerned, `through` is just a model with two foreign key fields rather than a many-to-many relation.

In all other respects, the `InlineModelAdmin` is exactly the same as any other. You can customize the appearance using any of the normal `ModelAdmin` properties.

## Working with many-to-many intermediary models

When you specify an intermediary model using the `through` argument to a `ManyToManyField`, the admin will not display a widget by default. This is because each instance of that intermediary model requires more information than could be displayed in a single widget, and the layout required for multiple widgets will vary depending on the intermediate model.

However, we still want to be able to edit that information inline. Fortunately, this is easy to do with inline admin models. Suppose we have the following models:

```
from django.db import models

class Person(models.Model):
    name = models.CharField(max_length=128)

class Group(models.Model):
    name = models.CharField(max_length=128)
    members = models.ManyToManyField(Person, through='Membership')

class Membership(models.Model):
    person = models.ForeignKey(Person, on_delete=models.CASCADE)
    group = models.ForeignKey(Group, on_delete=models.CASCADE)
    date_joined = models.DateField()
    invite_reason = models.CharField(max_length=64)
```

The first step in displaying this intermediate model in the admin is to define an inline class for the `Membership` model:

```
class MembershipInline(admin.TabularInline):
    model = Membership
    extra = 1
```

This simple example uses the default `InlineModelAdmin` values for the `Membership` model, and limits the extra add forms to one. This could be customized using any of the options available to `InlineModelAdmin` classes.

Now create admin views for the `Person` and `Group` models:

```
class PersonAdmin(admin.ModelAdmin):
    inlines = (MembershipInline,)

class GroupAdmin(admin.ModelAdmin):
    inlines = (MembershipInline,)
```

Finally, register your `Person` and `Group` models with the admin site:

```
admin.site.register(Person, PersonAdmin)
admin.site.register(Group, GroupAdmin)
```

Now your admin site is set up to edit `Membership` objects inline from either the `Person` or the `Group` detail pages.

## Using generic relations as an inline

It is possible to use an inline with generically related objects. Let's say you have the following models:

```
from django.db import models
from django.contrib.contenttypes.fields import GenericForeignKey

class Image(models.Model):
    image = models.ImageField(upload_to="images")
    content_type = models.ForeignKey(ContentType, on_delete=models.CASCADE)
    object_id = models.PositiveIntegerField()
    content_object = GenericForeignKey("content_type", "object_id")
```

```
class Product(models.Model):
    name = models.CharField(max_length=100)
```

If you want to allow editing and creating an `Image` instance on the `Product`, add/change views you can use `GenericTabularInline` or `GenericStackedInline` (both subclasses of `GenericInlineModelAdmin`) provided by `admin`. They implement tabular and stacked visual layouts for the forms representing the inline objects, respectively, just like their non-generic counterparts. They behave just like any other inline. In your `admin.py` for this example app:

```
from django.contrib import admin
from django.contrib.contenttypes.admin import GenericTabularInline

from myproject.myapp.models import Image, Product

class ImageInline(GenericTabularInline):
    model = Image

class ProductAdmin(admin.ModelAdmin):
    inlines = [
        ImageInline,
    ]

admin.site.register(Product, ProductAdmin)
```

See the [contenttypes documentation](#) for more specific information.

## Overriding admin templates

It is relatively easy to override many of the templates which the admin module uses to generate the various pages of an admin site. You can even override a few of these templates for a specific app, or a specific model.

### Set up your projects admin template directories

The admin template files are located in the `contrib/admin/templates/admin` directory.

In order to override one or more of them, first create an admin directory in your project's templates directory. This can be any of the directories you specified in the `DIRS` option of the `DjangoTemplates` backend in the `TEMPLATES` setting. If you have customized the `'loaders'` option, be sure `'django.template.loaders.filesystem.Loader'` appears before `'django.template.loaders.app_directories.Loader'` so that your custom templates will be found by the template loading system before those that are included with `django.contrib.admin`.

Within this admin directory, create sub-directories named after your app. Within these app subdirectories create sub-directories named after your models. Note, that the admin app will lowercase the model name when looking for the directory, so make sure you name the directory in all lowercase if you are going to run your app on a case-sensitive filesystem.

To override an admin template for a specific app, copy and edit the template from the `django/contrib/admin/templates/admin` directory, and save it to one of the directories you just created.

For example, if we wanted to add a tool to the change list view for all the models in an app named `my_app`, we would copy `contrib/admin/templates/admin/change_list.html` to the `templates/admin/my_app/` directory of our project, and make any necessary changes.

If we wanted to add a tool to the change list view for only a specific model named `'Page'`, we would copy that same file to the `templates/admin/my_app/page` directory of our project.

## Overriding vs. replacing an admin template

Because of the modular design of the admin templates, it is usually neither necessary nor advisable to replace an entire template. It is almost always better to override only the section of the template which you need to change.

To continue the example above, we want to add a new link next to the History tool for the Page model. After looking at `change_form.html` we determine that we only need to override the `object-tools-items` block. Therefore here is our new `change_form.html`:

```
{% extends "admin/change_form.html" %}
{% load i18n admin_urls %}
{% block object-tools-items %}
    <li>
        <a href="{% url opts|admin_urlname:'history' original.pk|admin_urlquote %}"_
↪class="historylink">{% trans "History" %}</a>
    </li>
    <li>
        <a href="mylink/" class="historylink">My Link</a>
    </li>
    {% if has_absolute_url %}
        <li>
            <a href="{% url 'admin:view_on_site' content_type_id original.pk %}"_
↪class="viewsitelink">{% trans "View on site" %}</a>
        </li>
    {% endif %}
{% endblock %}
```

And that's it! If we placed this file in the `templates/admin/my_app` directory, our link would appear on the change form for all models within `my_app`.

## Templates which may be overridden per app or model

Not every template in `contrib/admin/templates/admin` may be overridden per app or per model. The following can:

- `app_index.html`
- `change_form.html`
- `change_list.html`
- `delete_confirmation.html`
- `object_history.html`

For those templates that cannot be overridden in this way, you may still override them for your entire project. Just place the new version in your `templates/admin` directory. This is particularly useful to create custom 404 and 500 pages.

---

**Note:** Some of the admin templates, such as `change_list_results.html` are used to render custom inclusion tags. These may be overridden, but in such cases you are probably better off creating your own version of the tag in question and giving it a different name. That way you can use it selectively.

---

## Root and login templates

If you wish to change the index, login or logout templates, you are better off creating your own `AdminSite` instance (see below), and changing the `AdminSite.index_template`, `AdminSite.login_template` or `AdminSite.logout_template` properties.

## AdminSite objects

**class AdminSite** (*name='admin'*)

A Django administrative site is represented by an instance of `django.contrib.admin.sites.AdminSite`; by default, an instance of this class is created as `django.contrib.admin.site` and you can register your models and `ModelAdmin` instances with it.

When constructing an instance of an `AdminSite`, you can provide a unique instance name using the `name` argument to the constructor. This instance name is used to identify the instance, especially when *reversing admin URLs*. If no instance name is provided, a default instance name of `admin` will be used. See *Customizing the AdminSite class* for an example of customizing the `AdminSite` class.

## AdminSite attributes

Templates can override or extend base admin templates as described in *Overriding admin templates*.

`AdminSite.site_header`

The text to put at the top of each admin page, as an `<h1>` (a string). By default, this is “Django administration”.

`AdminSite.site_title`

The text to put at the end of each admin page’s `<title>` (a string). By default, this is “Django site admin”.

`AdminSite.site_url`

The URL for the “View site” link at the top of each admin page. By default, `site_url` is `/`. Set it to `None` to remove the link.

For sites running on a subpath, the `each_context()` method checks if the current request has `request.META['SCRIPT_NAME']` set and uses that value if `site_url` isn’t set to something other than `/`.

The `SCRIPT_NAME` support described in the previous paragraph was added.

`AdminSite.index_title`

The text to put at the top of the admin index page (a string). By default, this is “Site administration”.

`AdminSite.index_template`

Path to a custom template that will be used by the admin site main index view.

`AdminSite.app_index_template`

Path to a custom template that will be used by the admin site app index view.

`AdminSite.empty_value_display`

The string to use for displaying empty values in the admin site’s change list. Defaults to a dash. The value can also be overridden on a per `ModelAdmin` basis and on a custom field within a `ModelAdmin` by setting an `empty_value_display` attribute on the field. See *ModelAdmin.empty\_value\_display* for examples.

`AdminSite.login_template`

Path to a custom template that will be used by the admin site login view.

`AdminSite.login_form`

Subclass of `AuthenticationForm` that will be used by the admin site login view.

`AdminSite.logout_template`

Path to a custom template that will be used by the admin site logout view.

`AdminSite.password_change_template`

Path to a custom template that will be used by the admin site password change view.

`AdminSite.password_change_done_template`

Path to a custom template that will be used by the admin site password change done view.

## AdminSite methods

`AdminSite.each_context(request)`

Returns a dictionary of variables to put in the template context for every page in the admin site.

Includes the following variables and values by default:

- `site_header`: `AdminSite.site_header`
- `site_title`: `AdminSite.site_title`
- `site_url`: `AdminSite.site_url`
- `has_permission`: `AdminSite.has_permission()`
- `available_apps`: a list of applications from the *application registry* available for the current user. Each entry in the list is a dict representing an application with the following keys:
  - `app_label`: the application label
  - `app_url`: the URL of the application index in the admin
  - `has_module_perms`: a boolean indicating if displaying and accessing of the module's index page is permitted for the current user
  - `models`: a list of the models available in the application

Each model is a dict with the following keys:

- `object_name`: class name of the model
- `name`: plural name of the model
- `perms`: a dict tracking add, change, and delete permissions
- `admin_url`: admin changelist URL for the model
- `add_url`: admin URL to add a new model instance

The `available_apps` variable was added.

`AdminSite.has_permission(request)`

Returns True if the user for the given `HttpRequest` has permission to view at least one page in the admin site. Defaults to requiring both `User.is_active` and `User.is_staff` to be True.

`AdminSite.register(model_or_iterable, admin_class=None, **options)`

Registers the given model class (or iterable of classes) with the given `admin_class`. `admin_class` defaults to `ModelAdmin` (the default admin options). If keyword arguments are given – e.g. `list_display` – they'll be applied as options to the admin class.

Raises `ImproperlyConfigured` if a model is abstract. and `django.contrib.admin.sites.AlreadyRegistered` if a model is already registered.

## Hooking AdminSite instances into your URLconf

The last step in setting up the Django admin is to hook your `AdminSite` instance into your URLconf. Do this by pointing a given URL at the `AdminSite.urls` method. It is not necessary to use `include()`.

In this example, we register the default `AdminSite` instance `django.contrib.admin.site` at the URL `/admin/`

```
# urls.py
from django.conf.urls import url
from django.contrib import admin

urlpatterns = [
    url(r'^admin/', admin.site.urls),
]
```

In previous versions, you would pass `admin.site.urls` to `include()`.

## Customizing the AdminSite class

If you'd like to set up your own admin site with custom behavior, you're free to subclass `AdminSite` and override or add anything you like. Then, simply create an instance of your `AdminSite` subclass (the same way you'd instantiate any other Python class) and register your models and `ModelAdmin` subclasses with it instead of with the default site. Finally, update `myproject/urls.py` to reference your `AdminSite` subclass.

```
myapp/admin.py

from django.contrib.admin import AdminSite

from .models import MyModel

class MyAdminSite(AdminSite):
    site_header = 'Monty Python administration'

admin_site = MyAdminSite(name='myadmin')
admin_site.register(MyModel)
```

```
myproject/urls.py

from django.conf.urls import url

from myapp.admin import admin_site

urlpatterns = [
    url(r'^myadmin/', admin_site.urls),
]
```

Note that you may not want autodiscovery of admin modules when using your own `AdminSite` instance since you will likely be importing all the per-app admin modules in your `myproject.admin` module. This means you need to put `'django.contrib.admin.apps.SimpleAdminConfig'` instead of `'django.contrib.admin'` in your `INSTALLED_APPS` setting.

## Multiple admin sites in the same URLconf

It's easy to create multiple instances of the admin site on the same Django-powered website. Just create multiple instances of `AdminSite` and root each one at a different URL.

In this example, the URLs `/basic-admin/` and `/advanced-admin/` feature separate versions of the admin site – using the `AdminSite` instances `myproject.admin.basic_site` and `myproject.admin.advanced_site`, respectively:

```
# urls.py
from django.conf.urls import url
from myproject.admin import basic_site, advanced_site

urlpatterns = [
    url(r'^basic-admin/', basic_site.urls),
    url(r'^advanced-admin/', advanced_site.urls),
]
```

`AdminSite` instances take a single argument to their constructor, their name, which can be anything you like. This argument becomes the prefix to the URL names for the purposes of *reversing them*. This is only necessary if you are using more than one `AdminSite`.

### Adding views to admin sites

Just like `ModelAdmin`, `AdminSite` provides a `get_urls()` method that can be overridden to define additional views for the site. To add a new view to your admin site, extend the base `get_urls()` method to include a pattern for your new view.

---

**Note:** Any view you render that uses the admin templates, or extends the base admin template, should set `request.current_app` before rendering the template. It should be set to either `self.name` if your view is on an `AdminSite` or `self.admin_site.name` if your view is on a `ModelAdmin`.

---

### Adding a password-reset feature

You can add a password-reset feature to the admin site by adding a few lines to your `URLconf`. Specifically, add these four patterns:

```
from django.contrib.auth import views as auth_views

url(r'^admin/password_reset/$', auth_views.password_reset, name='admin_password_reset'),
url(r'^admin/password_reset/done/$', auth_views.password_reset_done, name='password_reset_done'),
url(r'^reset/(?P<uidb64>[0-9A-Za-z_-]+)/(?P<token>+)/$', auth_views.password_reset_confirm, name='password_reset_confirm'),
url(r'^reset/done/$', auth_views.password_reset_complete, name='password_reset_complete'),
```

(This assumes you’ve added the admin at `admin/` and requires that you put the URLs starting with `^admin/` before the line that includes the admin app itself).

The presence of the `admin_password_reset` named URL will cause a “forgotten your password?” link to appear on the default admin log-in page under the password box.

## LogEntry objects

### class `models.LogEntry`

The `LogEntry` class tracks additions, changes, and deletions of objects done through the admin interface.

## LogEntry attributes

### `LogEntry.action_time`

The date and time of the action.

### `LogEntry.user`

The user (an `AUTH_USER_MODEL` instance) who performed the action.

### `LogEntry.content_type`

The `ContentType` of the modified object.

### `LogEntry.object_id`

The textual representation of the modified object's primary key.

### `LogEntry.object_repr`

The object's `repr()` after the modification.

### `LogEntry.action_flag`

The type of action logged: `ADDITION`, `CHANGE`, `DELETION`.

For example, to get a list of all additions done through the admin:

```
from django.contrib.admin.models import LogEntry, ADDITION
LogEntry.objects.filter(action_flag=ADDITION)
```

### `LogEntry.change_message`

The detailed description of the modification. In the case of an edit, for example, the message contains a list of the edited fields. The Django admin site formats this content as a JSON structure, so that `get_change_message()` can recompose a message translated in the current user language. Custom code might set this as a plain string though. You are advised to use the `get_change_message()` method to retrieve this value instead of accessing it directly.

Previously, this attribute was always a plain string. It is now JSON-structured so that the message can be translated in the current user language. Old messages are untouched.

## LogEntry methods

### `LogEntry.get_edited_object()`

A shortcut that returns the referenced object.

### `LogEntry.get_change_message()`

Formats and translates `change_message` into the current user language. Messages created before Django 1.10 will always be displayed in the language in which they were logged.

## Reversing admin URLs

When an `AdminSite` is deployed, the views provided by that site are accessible using Django's *URL reversing system*.

The `AdminSite` provides the following named URL patterns:

Page	URL name	Parameters
Index	index	
Login	login	
Logout	logout	
Password change	password_change	
Password change done	password_change_done	
i18n JavaScript	jsi18n	
Application index page	app_list	app_label
Redirect to object's page	view_on_site	content_type_id, object_id

Each `ModelAdmin` instance provides an additional set of named URLs:

Page	URL name	Parameters
Changelist	{{ app_label }}_{{ model_name }}_changelist	
Add	{{ app_label }}_{{ model_name }}_add	
History	{{ app_label }}_{{ model_name }}_history	object_id
Delete	{{ app_label }}_{{ model_name }}_delete	object_id
Change	{{ app_label }}_{{ model_name }}_change	object_id

The `UserAdmin` provides a named URL:

Page	URL name	Parameters
Password change	auth_user_password_change	user_id

These named URLs are registered with the application namespace `admin`, and with an instance namespace corresponding to the name of the Site instance.

So - if you wanted to get a reference to the Change view for a particular `Choice` object (from the polls application) in the default admin, you would call:

```
>>> from django.urls import reverse
>>> c = Choice.objects.get(...)
>>> change_url = reverse('admin:polls_choice_change', args=(c.id,))
```

This will find the first registered instance of the admin application (whatever the instance name), and resolve to the view for changing `poll.Choice` instances in that instance.

If you want to find a URL in a specific admin instance, provide the name of that instance as a `current_app` hint to the reverse call. For example, if you specifically wanted the admin view from the admin instance named `custom`, you would need to call:

```
>>> change_url = reverse('admin:polls_choice_change', args=(c.id,), current_app=
↳ 'custom')
```

For more details, see the documentation on [reversing namespaced URLs](#).

To allow easier reversing of the admin urls in templates, Django provides an `admin_urlname` filter which takes an action as argument:

```
{% load admin_urls %}
<a href="{% url opts|admin_urlname:'add' %}">Add user</a>
<a href="{% url opts|admin_urlname:'delete' user.pk %}">Delete this user</a>
```

The action in the examples above match the last part of the URL names for `ModelAdmin` instances described above. The `opts` variable can be any object which has an `app_label` and `model_name` attributes and is usually supplied by the admin views for the current model.

## The `staff_member_required` decorator

**staff\_member\_required** (*redirect\_field\_name='next', login\_url='admin:login'*)

This decorator is used on the admin views that require authorization. A view decorated with this function will have the following behavior:

- If the user is logged in, is a staff member (`User.is_staff=True`), and is active (`User.is_active=True`), execute the view normally.
- Otherwise, the request will be redirected to the URL specified by the `login_url` parameter, with the originally requested path in a query string variable specified by `redirect_field_name`. For example: `/admin/login/?next=/admin/polls/question/3/`.

Example usage:

```
from django.contrib.admin.views.decorators import staff_member_required

@staff_member_required
def my_view(request):
    ...
```

## 6.5.2 `django.contrib.auth`

This document provides API reference material for the components of Django's authentication system. For more details on the usage of these components or how to customize authentication and authorization see the [authentication topic guide](#).

### User model

#### Fields

**class** `models.User`

*User* objects have the following fields:

#### **username**

Required. 150 characters or fewer. Usernames may contain alphanumeric, `_`, `@`, `+`, `.` and `-` characters.

The `max_length` should be sufficient for many use cases. If you need a longer length, please use a [custom user model](#). If you use MySQL with the `utf8mb4` encoding (recommended for proper Unicode support), specify at most `max_length=191` because MySQL can only create unique indexes with 191 characters in that case by default.

---

#### **Usernames and Unicode**

Django originally accepted only ASCII letters in usernames. Although it wasn't a deliberate choice, Unicode characters have always been accepted when using Python 3. Django 1.10 officially added Unicode support in usernames, keeping the ASCII-only behavior on Python 2.

---

The `max_length` increased from 30 to 150 characters.

#### **first\_name**

Optional. 30 characters or fewer.

#### **last\_name**

Optional. 30 characters or fewer.

**email**

Optional. Email address.

**password**

Required. A hash of, and metadata about, the password. (Django doesn't store the raw password.) Raw passwords can be arbitrarily long and can contain any character. See the [password documentation](#).

**groups**

Many-to-many relationship to [Group](#)

**user\_permissions**

Many-to-many relationship to [Permission](#)

**is\_staff**

Boolean. Designates whether this user can access the admin site.

**is\_active**

Boolean. Designates whether this user account should be considered active. We recommend that you set this flag to `False` instead of deleting accounts; that way, if your applications have any foreign keys to users, the foreign keys won't break.

This doesn't necessarily control whether or not the user can log in. Authentication backends aren't required to check for the `is_active` flag but the default backend ([ModelBackend](#)) and the [RemoteUserBackend](#) do. You can use [AllowAllUsersModelBackend](#) or [AllowAllUsersRemoteUserBackend](#) if you want to allow inactive users to login. In this case, you'll also want to customize the [AuthenticationForm](#) used by the `login()` view as it rejects inactive users. Be aware that the permission-checking methods such as `has_perm()` and the authentication in the Django admin all return `False` for inactive users.

In older versions, [ModelBackend](#) and [RemoteUserBackend](#) allowed inactive users to authenticate.

**is\_superuser**

Boolean. Designates that this user has all permissions without explicitly assigning them.

**last\_login**

A datetime of the user's last login.

**date\_joined**

A datetime designating when the account was created. Is set to the current date/time by default when the account is created.

## Attributes

**class** `models.User`**is\_authenticated**

Read-only attribute which is always `True` (as opposed to `AnonymousUser.is_authenticated` which is always `False`). This is a way to tell if the user has been authenticated. This does not imply any permissions and doesn't check if the user is active or has a valid session. Even though normally you will check this attribute on `request.user` to find out whether it has been populated by the [AuthenticationMiddleware](#) (representing the currently logged-in user), you should know this attribute is `True` for any [User](#) instance.

In older versions, this was a method. Backwards-compatibility support for using it as a method will be removed in Django 2.0.

**is\_anonymous**

Read-only attribute which is always `False`. This is a way of differentiating `User` and `AnonymousUser` objects. Generally, you should prefer using `is_authenticated` to this attribute.

In older versions, this was a method. Backwards-compatibility support for using it as a method will be removed in Django 2.0.

**Methods**

`class models.User`

**get\_username()**

Returns the username for the user. Since the `User` model can be swapped out, you should use this method instead of referencing the username attribute directly.

**get\_full\_name()**

Returns the `first_name` plus the `last_name`, with a space in between.

**get\_short\_name()**

Returns the `first_name`.

**set\_password(raw\_password)**

Sets the user's password to the given raw string, taking care of the password hashing. Doesn't save the `User` object.

When the `raw_password` is `None`, the password will be set to an unusable password, as if `set_unusable_password()` were used.

**check\_password(raw\_password)**

Returns `True` if the given raw string is the correct password for the user. (This takes care of the password hashing in making the comparison.)

**set\_unusable\_password()**

Marks the user as having no password set. This isn't the same as having a blank string for a password. `check_password()` for this user will never return `True`. Doesn't save the `User` object.

You may need this if authentication for your application takes place against an existing external source such as an LDAP directory.

**has\_usable\_password()**

Returns `False` if `set_unusable_password()` has been called for this user.

**get\_group\_permissions(obj=None)**

Returns a set of permission strings that the user has, through their groups.

If `obj` is passed in, only returns the group permissions for this specific object.

**get\_all\_permissions(obj=None)**

Returns a set of permission strings that the user has, both through group and user permissions.

If `obj` is passed in, only returns the permissions for this specific object.

**has\_perm(perm, obj=None)**

Returns `True` if the user has the specified permission, where `perm` is in the format "`<app label>.<permission codename>`". (see documentation on [permissions](#)). If the user is inactive, this method will always return `False`.

If `obj` is passed in, this method won't check for a permission for the model, but for this specific object.

**has\_perms** (*perm\_list*, *obj=None*)

Returns True if the user has each of the specified permissions, where each perm is in the format "<app label>.<permission codename>". If the user is inactive, this method will always return False.

If *obj* is passed in, this method won't check for permissions for the model, but for the specific object.

**has\_module\_perms** (*package\_name*)

Returns True if the user has any permissions in the given package (the Django app label). If the user is inactive, this method will always return False.

**email\_user** (*subject*, *message*, *from\_email=None*, *\*\*kwargs*)

Sends an email to the user. If *from\_email* is None, Django uses the `DEFAULT_FROM_EMAIL`. Any *\*\*kwargs* are passed to the underlying `send_mail()` call.

## Manager methods

**class** `models.UserManager`

The `User` model has a custom manager that has the following helper methods (in addition to the methods provided by `BaseUserManager`):

**create\_user** (*username*, *email=None*, *password=None*, *\*\*extra\_fields*)

Creates, saves and returns a `User`.

The *username* and *password* are set as given. The domain portion of *email* is automatically converted to lowercase, and the returned `User` object will have `is_active` set to True.

If no password is provided, `set_unusable_password()` will be called.

The *extra\_fields* keyword arguments are passed through to the `User`'s `__init__` method to allow setting arbitrary fields on a *custom user model*.

See *Creating users* for example usage.

**create\_superuser** (*username*, *email*, *password*, *\*\*extra\_fields*)

Same as `create_user()`, but sets `is_staff` and `is_superuser` to True.

## AnonymousUser object

**class** `models.AnonymousUser`

`django.contrib.auth.models.AnonymousUser` is a class that implements the `django.contrib.auth.models.User` interface, with these differences:

- *id* is always None.
- *username* is always the empty string.
- `get_username()` always returns the empty string.
- `is_anonymous` is True instead of False.
- `is_authenticated` is False instead of True.
- `is_staff` and `is_superuser` are always False.
- `is_active` is always False.
- `groups` and `user_permissions` are always empty.
- `set_password()`, `check_password()`, `save()` and `delete()` raise `NotImplementedError`.

In practice, you probably won't need to use *AnonymousUser* objects on your own, but they're used by Web requests, as explained in the next section.

## Permission model

```
class models.Permission
```

### Fields

*Permission* objects have the following fields:

```
class models.Permission
```

**name**

Required. 255 characters or fewer. Example: 'Can vote'.

**content\_type**

Required. A reference to the `django_content_type` database table, which contains a record for each installed model.

**codename**

Required. 100 characters or fewer. Example: 'can\_vote'.

### Methods

*Permission* objects have the standard data-access methods like any other *Django model*.

## Group model

```
class models.Group
```

### Fields

*Group* objects have the following fields:

```
class models.Group
```

**name**

Required. 80 characters or fewer. Any characters are permitted. Example: 'Awesome Users'.

**permissions**

Many-to-many field to *Permission*:

```
group.permissions.set([permission_list])
group.permissions.add(permission, permission, ...)
group.permissions.remove(permission, permission, ...)
group.permissions.clear()
```

## Validators

### `class validators.ASCIIUsernameValidator`

A field validator allowing only ASCII letters, in addition to @, ., +, -, and \_. The default validator for `User.username` on Python 2.

### `class validators.UnicodeUsernameValidator`

A field validator allowing Unicode letters, in addition to @, ., +, -, and \_. The default validator for `User.username` on Python 3.

## Login and logout signals

The auth framework uses the following *signals* that can be used for notification when a user logs in or out.

### `user_logged_in()`

Sent when a user logs in successfully.

Arguments sent with this signal:

**sender** The class of the user that just logged in.

**request** The current `HttpRequest` instance.

**user** The user instance that just logged in.

### `user_logged_out()`

Sent when the logout method is called.

**sender** As above: the class of the user that just logged out or `None` if the user was not authenticated.

**request** The current `HttpRequest` instance.

**user** The user instance that just logged out or `None` if the user was not authenticated.

### `user_login_failed()`

Sent when the user failed to login successfully

**sender** The name of the module used for authentication.

**credentials** A dictionary of keyword arguments containing the user credentials that were passed to `authenticate()` or your own custom authentication backend. Credentials matching a set of ‘sensitive’ patterns, (including password) will not be sent in the clear as part of the signal.

## Authentication backends

This section details the authentication backends that come with Django. For information on how to use them and how to write your own authentication backends, see the *Other authentication sources section* of the *User authentication guide*.

## Available authentication backends

The following backends are available in `django.contrib.auth.backends`:

### `class ModelBackend`

This is the default authentication backend used by Django. It authenticates using credentials consisting of a user identifier and password. For Django’s default user model, the user identifier is the username, for custom user models it is the field specified by `USERNAME_FIELD` (see *Customizing Users and authentication*).

It also handles the default permissions model as defined for `User` and `PermissionsMixin`.

`has_perm()`, `get_all_permissions()`, `get_user_permissions()`, and `get_group_permissions()` allow an object to be passed as a parameter for object-specific permissions, but this backend does not implement them other than returning an empty set of permissions if `obj` is not `None`.

**authenticate** (*username=None, password=None, \*\*kwargs*)

Tries to authenticate `username` with `password` by calling `User.check_password`. If no `username` is provided, it tries to fetch a `username` from `kwargs` using the key `CustomUser.USERNAME_FIELD`. Returns an authenticated user or `None`.

**get\_user\_permissions** (*user\_obj, obj=None*)

Returns the set of permission strings the `user_obj` has from their own user permissions. Returns an empty set if `is_anonymous` or `is_active` is `False`.

**get\_group\_permissions** (*user\_obj, obj=None*)

Returns the set of permission strings the `user_obj` has from the permissions of the groups they belong. Returns an empty set if `is_anonymous` or `is_active` is `False`.

**get\_all\_permissions** (*user\_obj, obj=None*)

Returns the set of permission strings the `user_obj` has, including both user permissions and group permissions. Returns an empty set if `is_anonymous` or `is_active` is `False`.

**has\_perm** (*user\_obj, perm, obj=None*)

Uses `get_all_permissions()` to check if `user_obj` has the permission string `perm`. Returns `False` if the user is not `is_active`.

**has\_module\_perms** (*self, user\_obj, app\_label*)

Returns whether the `user_obj` has any permissions on the app `app_label`.

**user\_can\_authenticate** ()

Returns whether the user is allowed to authenticate. To match the behavior of `AuthenticationForm` which *prohibits inactive users from logging in*, this method returns `False` for users with `is_active=False`. Custom user models that don't have an `is_active` field are allowed.

#### class AllowAllUsersModelBackend

Same as `ModelBackend` except that it doesn't reject inactive users because `user_can_authenticate()` always returns `True`.

When using this backend, you'll likely want to customize the `AuthenticationForm` used by the `login()` view by overriding the `confirm_login_allowed()` method as it rejects inactive users.

#### class RemoteUserBackend

Use this backend to take advantage of external-to-Django-handled authentication. It authenticates using usernames passed in `request.META['REMOTE_USER']`. See the *Authenticating against REMOTE\_USER* documentation.

If you need more control, you can create your own authentication backend that inherits from this class and override these attributes or methods:

`RemoteUserBackend.create_unknown_user`

`True` or `False`. Determines whether or not a user object is created if not already in the database Defaults to `True`.

`RemoteUserBackend.authenticate` (*remote\_user*)

The `username` passed as `remote_user` is considered trusted. This method simply returns the user object with the given `username`, creating a new user object if `create_unknown_user` is `True`.

Returns `None` if `create_unknown_user` is `False` and a `User` object with the given `username` is not found in the database.

`RemoteUserBackend.clean_username(username)`

Performs any cleaning on the `username` (e.g. stripping LDAP DN information) prior to using it to get or create a user object. Returns the cleaned username.

`RemoteUserBackend.configure_user(user)`

Configures a newly created user. This method is called immediately after a new user is created, and can be used to perform custom setup actions, such as setting the user's groups based on attributes in an LDAP directory. Returns the user object.

`RemoteUserBackend.user_can_authenticate()`

Returns whether the user is allowed to authenticate. This method returns `False` for users with `is_active=False`. Custom user models that don't have an `is_active` field are allowed.

**class `AllowAllUsersRemoteUserBackend`**

Same as `RemoteUserBackend` except that it doesn't reject inactive users because `user_can_authenticate` always returns `True`.

## Utility functions

`get_user(request)`

Returns the user model instance associated with the given request's session.

It checks if the authentication backend stored in the session is present in `AUTHENTICATION_BACKENDS`. If so, it uses the backend's `get_user()` method to retrieve the user model instance and then verifies the session by calling the user model's `get_session_auth_hash()` method.

Returns an instance of `AnonymousUser` if the authentication backend stored in the session is no longer in `AUTHENTICATION_BACKENDS`, if a user isn't returned by the backend's `get_user()` method, or if the session auth hash doesn't validate.

## 6.5.3 The contenttypes framework

Django includes a `contenttypes` application that can track all of the models installed in your Django-powered project, providing a high-level, generic interface for working with your models.

### Overview

At the heart of the `contenttypes` application is the `ContentType` model, which lives at `django.contrib.contenttypes.models.ContentType`. Instances of `ContentType` represent and store information about the models installed in your project, and new instances of `ContentType` are automatically created whenever new models are installed.

Instances of `ContentType` have methods for returning the model classes they represent and for querying objects from those models. `ContentType` also has a *custom manager* that adds methods for working with `ContentType` and for obtaining instances of `ContentType` for a particular model.

Relations between your models and `ContentType` can also be used to enable “generic” relationships between an instance of one of your models and instances of any model you have installed.

### Installing the contenttypes framework

The `contenttypes` framework is included in the default `INSTALLED_APPS` list created by `django-admin startproject`, but if you've removed it or if you manually set up your `INSTALLED_APPS` list, you can enable it by adding `'django.contrib.contenttypes'` to your `INSTALLED_APPS` setting.

It's generally a good idea to have the `contenttypes` framework installed; several of Django's other bundled applications require it:

- The admin application uses it to log the history of each object added or changed through the admin interface.
- Django's *authentication framework* uses it to tie user permissions to specific models.

## The `ContentType` model

### class `ContentType`

Each instance of `ContentType` has two fields which, taken together, uniquely describe an installed model:

#### `app_label`

The name of the application the model is part of. This is taken from the `app_label` attribute of the model, and includes only the *last* part of the application's Python import path; `django.contrib.contenttypes`, for example, becomes an `app_label` of `contenttypes`.

#### `model`

The name of the model class.

Additionally, the following property is available:

#### `name`

The human-readable name of the content type. This is taken from the `verbose_name` attribute of the model.

Let's look at an example to see how this works. If you already have the `contenttypes` application installed, and then add *the sites application* to your `INSTALLED_APPS` setting and run `manage.py migrate` to install it, the model `django.contrib.sites.models.Site` will be installed into your database. Along with it a new instance of `ContentType` will be created with the following values:

- `app_label` will be set to `'sites'` (the last part of the Python path `django.contrib.sites`).
- `model` will be set to `'site'`.

## Methods on `ContentType` instances

Each `ContentType` instance has methods that allow you to get from a `ContentType` instance to the model it represents, or to retrieve objects from that model:

`ContentType.get_object_for_this_type(**kwargs)`

Takes a set of valid *lookup arguments* for the model the `ContentType` represents, and does a `get()` *lookup* on that model, returning the corresponding object.

`ContentType.model_class()`

Returns the model class represented by this `ContentType` instance.

For example, we could look up the `ContentType` for the `User` model:

```
>>> from django.contrib.contenttypes.models import ContentType
>>> ContentType.objects.get(app_label="auth", model="user")
<ContentType: user>
```

And then use it to query for a particular `User`, or to get access to the `User` model class:

```
>>> user_type.model_class()
<class 'django.contrib.auth.models.User'>
>>> user_type.get_object_for_this_type(username='Guido')
<User: Guido>
```

Together, `get_object_for_this_type()` and `model_class()` enable two extremely important use cases:

1. Using these methods, you can write high-level generic code that performs queries on any installed model – instead of importing and using a single specific model class, you can pass an `app_label` and `model` into a `ContentType` lookup at runtime, and then work with the model class or retrieve objects from it.
2. You can relate another model to `ContentType` as a way of tying instances of it to particular model classes, and use these methods to get access to those model classes.

Several of Django’s bundled applications make use of the latter technique. For example, *the permissions system* in Django’s authentication framework uses a `Permission` model with a foreign key to `ContentType`; this lets `Permission` represent concepts like “can add blog entry” or “can delete news story”.

## The ContentTypeManager

### class ContentTypeManager

`ContentType` also has a custom manager, `ContentTypeManager`, which adds the following methods:

#### `clear_cache()`

Clears an internal cache used by `ContentType` to keep track of models for which it has created `ContentType` instances. You probably won’t ever need to call this method yourself; Django will call it automatically when it’s needed.

#### `get_for_id(id)`

Lookup a `ContentType` by ID. Since this method uses the same shared cache as `get_for_model()`, it’s preferred to use this method over the usual `ContentType.objects.get(pk=id)`

#### `get_for_model(model, for_concrete_model=True)`

Takes either a model class or an instance of a model, and returns the `ContentType` instance representing that model. `for_concrete_model=False` allows fetching the `ContentType` of a proxy model.

#### `get_for_models(*models, for_concrete_models=True)`

Takes a variadic number of model classes, and returns a dictionary mapping the model classes to the `ContentType` instances representing them. `for_concrete_models=False` allows fetching the `ContentType` of proxy models.

#### `get_by_natural_key(app_label, model)`

Returns the `ContentType` instance uniquely identified by the given application label and model name. The primary purpose of this method is to allow `ContentType` objects to be referenced via a *natural key* during deserialization.

The `get_for_model()` method is especially useful when you know you need to work with a `ContentType` but don’t want to go to the trouble of obtaining the model’s metadata to perform a manual lookup:

```
>>> from django.contrib.auth.models import User
>>> ContentType.objects.get_for_model(User)
<ContentType: user>
```

## Generic relations

Adding a foreign key from one of your own models to `ContentType` allows your model to effectively tie itself to another model class, as in the example of the `Permission` model above. But it’s possible to go one step further and use `ContentType` to enable truly generic (sometimes called “polymorphic”) relationships between models.

A simple example is a tagging system, which might look like this:

```

from django.db import models
from django.contrib.contenttypes.fields import GenericForeignKey
from django.contrib.contenttypes.models import ContentType

class TaggedItem(models.Model):
    tag = models.SlugField()
    content_type = models.ForeignKey(ContentType, on_delete=models.CASCADE)
    object_id = models.PositiveIntegerField()
    content_object = GenericForeignKey('content_type', 'object_id')

    def __str__(self):
        # __unicode__ on Python 2
        return self.tag

```

A normal *ForeignKey* can only “point to” one other model, which means that if the *TaggedItem* model used a *ForeignKey* it would have to choose one and only one model to store tags for. The *contenttypes* application provides a special field type (*GenericForeignKey*) which works around this and allows the relationship to be with any model:

#### class *GenericForeignKey*

There are three parts to setting up a *GenericForeignKey*:

1. Give your model a *ForeignKey* to *ContentType*. The usual name for this field is “content\_type”.
2. Give your model a field that can store primary key values from the models you’ll be relating to. For most models, this means a *PositiveIntegerField*. The usual name for this field is “object\_id”.
3. Give your model a *GenericForeignKey*, and pass it the names of the two fields described above. If these fields are named “content\_type” and “object\_id”, you can omit this – those are the default field names *GenericForeignKey* will look for.

#### for\_concrete\_model

If `False`, the field will be able to reference proxy models. Default is `True`. This mirrors the `for_concrete_model` argument to `get_for_model()`.

---

### Primary key type compatibility

The “object\_id” field doesn’t have to be the same type as the primary key fields on the related models, but their primary key values must be coercible to the same type as the “object\_id” field by its `get_db_prep_value()` method.

For example, if you want to allow generic relations to models with either *IntegerField* or *CharField* primary key fields, you can use *CharField* for the “object\_id” field on your model since integers can be coerced to strings by `get_db_prep_value()`.

For maximum flexibility you can use a *TextField* which doesn’t have a maximum length defined, however this may incur significant performance penalties depending on your database backend.

There is no one-size-fits-all solution for which field type is best. You should evaluate the models you expect to be pointing to and determine which solution will be most effective for your use case.

---

### Serializing references to *ContentType* objects

If you’re serializing data (for example, when generating *fixtures*) from a model that implements generic relations, you should probably be using a natural key to uniquely identify related *ContentType* objects. See *natural keys* and `dumpdata --natural-foreign` for more information.

This will enable an API similar to the one used for a normal *ForeignKey*; each *TaggedItem* will have a `content_object` field that returns the object it’s related to, and you can also assign to that field or use it when

creating a TaggedItem:

```
>>> from django.contrib.auth.models import User
>>> guido = User.objects.get(username='Guido')
>>> t = TaggedItem(content_object=guido, tag='bdf1')
>>> t.save()
>>> t.content_object
<User: Guido>
```

Due to the way *GenericForeignKey* is implemented, you cannot use such fields directly with filters (`filter()` and `exclude()`, for example) via the database API. Because a *GenericForeignKey* isn't a normal field object, these examples will *not* work:

```
# This will fail
>>> TaggedItem.objects.filter(content_object=guido)
# This will also fail
>>> TaggedItem.objects.get(content_object=guido)
```

Likewise, *GenericForeignKeys* does not appear in *ModelForms*.

## Reverse generic relations

### class GenericRelation

#### related\_query\_name

The relation on the related object back to this object doesn't exist by default. Setting `related_query_name` creates a relation from the related object back to this one. This allows querying and filtering from the related object.

If you know which models you'll be using most often, you can also add a "reverse" generic relationship to enable an additional API. For example:

```
from django.db import models
from django.contrib.contenttypes.fields import GenericRelation

class Bookmark(models.Model):
    url = models.URLField()
    tags = GenericRelation(TaggedItem)
```

Bookmark instances will each have a `tags` attribute, which can be used to retrieve their associated TaggedItems:

```
>>> b = Bookmark(url='https://www.djangoproject.com/')
>>> b.save()
>>> t1 = TaggedItem(content_object=b, tag='django')
>>> t1.save()
>>> t2 = TaggedItem(content_object=b, tag='python')
>>> t2.save()
>>> b.tags.all()
<QuerySet [<TaggedItem: django>, <TaggedItem: python>]>
```

Defining *GenericRelation* with `related_query_name` set allows querying from the related object:

```
tags = GenericRelation(TaggedItem, related_query_name='bookmarks')
```

This enables filtering, ordering, and other query operations on *Bookmark* from *TaggedItem*:

```
>>> # Get all tags belonging to bookmarks containing `django` in the url
>>> TaggedItem.objects.filter(bookmarks__url__contains='django')
<QuerySet [<TaggedItem: django>, <TaggedItem: python>]>
```

Of course, if you don't add the reverse relationship, you can do the same types of lookups manually:

```
>>> b = Bookmark.objects.get(url='https://www.djangoproject.com/')
>>> bookmark_type = ContentType.objects.get_for_model(b)
>>> TaggedItem.objects.filter(content_type__pk=bookmark_type.id, object_id=b.id)
<QuerySet [<TaggedItem: django>, <TaggedItem: python>]>
```

Just as *GenericForeignKey* accepts the names of the content-type and object-ID fields as arguments, so too does *GenericRelation*; if the model which has the generic foreign key is using non-default names for those fields, you must pass the names of the fields when setting up a *GenericRelation* to it. For example, if the *TaggedItem* model referred to above used fields named `content_type_fk` and `object_primary_key` to create its generic foreign key, then a *GenericRelation* back to it would need to be defined like so:

```
tags = GenericRelation(
    TaggedItem,
    content_type_field='content_type_fk',
    object_id_field='object_primary_key',
)
```

Note also, that if you delete an object that has a *GenericRelation*, any objects which have a *GenericForeignKey* pointing at it will be deleted as well. In the example above, this means that if a *Bookmark* object were deleted, any *TaggedItem* objects pointing at it would be deleted at the same time.

Unlike *ForeignKey*, *GenericForeignKey* does not accept an `on_delete` argument to customize this behavior; if desired, you can avoid the cascade-deletion simply by not using *GenericRelation*, and alternate behavior can be provided via the `pre_delete` signal.

## Generic relations and aggregation

*Django's database aggregation API* works with a *GenericRelation*. For example, you can find out how many tags all the bookmarks have:

```
>>> Bookmark.objects.aggregate(Count('tags'))
{'tags__count': 3}
```

## Generic relation in forms

The `django.contrib.contenttypes.forms` module provides:

- *BaseGenericInlineFormSet*
- A formset factory, `generic_inlineformset_factory()`, for use with *GenericForeignKey*.

**class BaseGenericInlineFormSet**

**generic\_inlineformset\_factory**(*model*, *form*=*ModelForm*, *formset*=*BaseGenericInlineFormSet*, *ct\_field*="content\_type", *fk\_field*="object\_id", *fields*=*None*, *exclude*=*None*, *extra*=3, *can\_order*=*False*, *can\_delete*=*True*, *max\_num*=*None*, *formfield\_callback*=*None*, *validate\_max*=*False*, *for\_concrete\_model*=*True*, *min\_num*=*None*, *validate\_min*=*False*)

Returns a *GenericInlineFormSet* using `modelformset_factory()`.

You must provide `ct_field` and `fk_field` if they are different from the defaults, `content_type` and `object_id` respectively. Other parameters are similar to those documented in `modelformset_factory()` and `inlineformset_factory()`.

The `for_concrete_model` argument corresponds to the `for_concrete_model` argument on `GenericForeignKey`.

## Generic relations in admin

The `django.contrib.contenttypes.admin` module provides `GenericTabularInline` and `GenericStackedInline` (subclasses of `GenericInlineModelAdmin`)

These classes and functions enable the use of generic relations in forms and the admin. See the `model formset` and `admin` documentation for more information.

### class `GenericInlineModelAdmin`

The `GenericInlineModelAdmin` class inherits all properties from an `InlineModelAdmin` class. However, it adds a couple of its own for working with the generic relation:

#### `ct_field`

The name of the `ContentType` foreign key field on the model. Defaults to `content_type`.

#### `ct_fk_field`

The name of the integer field that represents the ID of the related object. Defaults to `object_id`.

### class `GenericTabularInline`

### class `GenericStackedInline`

Subclasses of `GenericInlineModelAdmin` with stacked and tabular layouts, respectively.

## 6.5.4 The flatpages app

Django comes with an optional “flatpages” application. It lets you store simple “flat” HTML content in a database and handles the management for you via Django’s admin interface and a Python API.

A flatpage is a simple object with a URL, title and content. Use it for one-off, special-case pages, such as “About” or “Privacy Policy” pages, that you want to store in a database but for which you don’t want to develop a custom Django application.

A flatpage can use a custom template or a default, systemwide flatpage template. It can be associated with one, or multiple, sites.

The content field may optionally be left blank if you prefer to put your content in a custom template.

Here are some examples of flatpages on Django-powered sites:

- <http://www.lawrence.com/about/contact/>
- <http://www2.ljworld.com/site/rules/>

## Installation

To install the flatpages app, follow these steps:

1. Install the `sites framework` by adding `'django.contrib.sites'` to your `INSTALLED_APPS` setting, if it’s not already in there.

Also make sure you've correctly set `SITE_ID` to the ID of the site the settings file represents. This will usually be 1 (i.e. `SITE_ID = 1`, but if you're using the sites framework to manage multiple sites, it could be the ID of a different site).

2. Add `'django.contrib.flatpages'` to your `INSTALLED_APPS` setting.

Then either:

3. Add an entry in your URLconf. For example:

```
urlpatterns = [
    url(r'^pages/', include('django.contrib.flatpages.urls')),
]
```

or:

3. Add `'django.contrib.flatpages.middleware.FlatpageFallbackMiddleware'` to your `MIDDLEWARE` setting.
4. Run the command `manage.py migrate`.

## How it works

`manage.py migrate` creates two tables in your database: `django_flatpage` and `django_flatpage_sites`. `django_flatpage` is a simple lookup table that simply maps a URL to a title and bunch of text content. `django_flatpage_sites` associates a flatpage with a site.

## Using the URLconf

There are several ways to include the flat pages in your URLconf. You can dedicate a particular path to flat pages:

```
urlpatterns = [
    url(r'^pages/', include('django.contrib.flatpages.urls')),
]
```

You can also set it up as a “catchall” pattern. In this case, it is important to place the pattern at the end of the other `urlpatterns`:

```
from django.contrib.flatpages import views

# Your other patterns here
urlpatterns += [
    url(r'^(?P<url>.*\/)$', views.flatpage),
]
```

**Warning:** If you set `APPEND_SLASH` to `False`, you must remove the slash in the catchall pattern or flatpages without a trailing slash will not be matched.

Another common setup is to use flat pages for a limited set of known pages and to hard code the urls, so you can reference them with the `url` template tag:

```
from django.contrib.flatpages import views

urlpatterns += [
    url(r'^about-us/$', views.flatpage, {'url': '/about-us/'}),
]
```

```
url(r'^license/$', views.flatpage, {'url': '/license/'}, name='license'),
]
```

## Using the middleware

The `FlatpageFallbackMiddleware` can do all of the work.

### class `FlatpageFallbackMiddleware`

Each time any Django application raises a 404 error, this middleware checks the flatpages database for the requested URL as a last resort. Specifically, it checks for a flatpage with the given URL with a site ID that corresponds to the `SITE_ID` setting.

If it finds a match, it follows this algorithm:

- If the flatpage has a custom template, it loads that template. Otherwise, it loads the template `flatpages/default.html`.
- It passes that template a single context variable, `flatpage`, which is the flatpage object. It uses `RequestContext` in rendering the template.

The middleware will only add a trailing slash and redirect (by looking at the `APPEND_SLASH` setting) if the resulting URL refers to a valid flatpage. Redirects are permanent (301 status code).

If it doesn't find a match, the request continues to be processed as usual.

The middleware only gets activated for 404s – not for 500s or responses of any other status code.

---

### Flatpages will not apply view middleware

Because the `FlatpageFallbackMiddleware` is applied only after URL resolution has failed and produced a 404, the response it returns will not apply any *view middleware* methods. Only requests which are successfully routed to a view via normal URL resolution apply view middleware.

Note that the order of `MIDDLEWARE` matters. Generally, you can put `FlatpageFallbackMiddleware` at the end of the list. This means it will run first when processing the response, and ensures that any other response-processing middlewares see the real flatpage response rather than the 404.

For more on middleware, read the *middleware docs*.

---

### Ensure that your 404 template works

Note that the `FlatpageFallbackMiddleware` only steps in once another view has successfully produced a 404 response. If another view or middleware class attempts to produce a 404 but ends up raising an exception instead, the response will become an HTTP 500 (“Internal Server Error”) and the `FlatpageFallbackMiddleware` will not attempt to serve a flat page.

---

## How to add, change and delete flatpages

### Via the admin interface

If you've activated the automatic Django admin interface, you should see a “Flatpages” section on the admin index page. Edit flatpages as you edit any other object in the system.

The `FlatPage` model has an `enable_comments` field that isn't used by `contrib.flatpages`, but that could be useful for your project or third-party apps. It doesn't appear in the admin interface, but you can add it by registering a custom `ModelAdmin` for `FlatPage`:

```
from django.contrib import admin
from django.contrib.flatpages.admin import FlatPageAdmin
from django.contrib.flatpages.models import FlatPage
from django.utils.translation import ugettext_lazy as _

# Define a new FlatPageAdmin
class FlatPageAdmin(FlatPageAdmin):
    fieldsets = (
        (None, {'fields': ('url', 'title', 'content', 'sites')}),
        (_('Advanced options'), {
            'classes': ('collapse', ),
            'fields': (
                'enable_comments',
                'registration_required',
                'template_name',
            ),
        }),
    )

# Re-register FlatPageAdmin
admin.site.unregister(FlatPage)
admin.site.register(FlatPage, FlatPageAdmin)
```

The `enable_comments` field was removed from `FlatPageAdmin`.

## Via the Python API

### class FlatPage

Flatpages are represented by a standard *Django model*, which lives in `django/contrib/flatpages/models.py`. You can access flatpage objects via the *Django database API*.

---

### Check for duplicate flatpage URLs.

If you add or modify flatpages via your own code, you will likely want to check for duplicate flatpage URLs within the same site. The flatpage form used in the admin performs this validation check, and can be imported from `django.contrib.flatpages.forms.FlatpageForm` and used in your own views.

---

## Flatpage templates

By default, flatpages are rendered via the template `flatpages/default.html`, but you can override that for a particular flatpage: in the admin, a collapsed fieldset titled “Advanced options” (clicking will expand it) contains a field for specifying a template name. If you're creating a flat page via the Python API you can simply set the template name as the field `template_name` on the `FlatPage` object.

Creating the `flatpages/default.html` template is your responsibility; in your template directory, just create a `flatpages` directory containing a file `default.html`.

Flatpage templates are passed a single context variable, `flatpage`, which is the flatpage object.

Here's a sample `flatpages/default.html` template:

```
<!DOCTYPE html>
<html>
<head>
<title>{{ flatpage.title }}</title>
</head>
<body>
{{ flatpage.content }}
</body>
</html>
```

Since you're already entering raw HTML into the admin page for a flatpage, both `flatpage.title` and `flatpage.content` are marked as **not** requiring *automatic HTML escaping* in the template.

## Getting a list of FlatPage objects in your templates

The flatpages app provides a template tag that allows you to iterate over all of the available flatpages on the *current site*.

Like all custom template tags, you'll need to *load its custom tag library* before you can use it. After loading the library, you can retrieve all current flatpages via the `get_flatpages` tag:

```
{% load flatpages %}
{% get_flatpages as flatpages %}
<ul>
  {% for page in flatpages %}
    <li><a href="{{ page.url }}">{{ page.title }}</a></li>
  {% endfor %}
</ul>
```

## Displaying registration\_required flatpages

By default, the `get_flatpages` templatetag will only show flatpages that are marked `registration_required = False`. If you want to display registration-protected flatpages, you need to specify an authenticated user using a `for` clause.

For example:

```
{% get_flatpages for someuser as about_pages %}
```

If you provide an anonymous user, `get_flatpages` will behave the same as if you hadn't provided a user – i.e., it will only show you public flatpages.

## Limiting flatpages by base URL

An optional argument, `starts_with`, can be applied to limit the returned pages to those beginning with a particular base URL. This argument may be passed as a string, or as a variable to be resolved from the context.

For example:

```
{% get_flatpages '/about/' as about_pages %}
{% get_flatpages about_prefix as about_pages %}
{% get_flatpages '/about/' for someuser as about_pages %}
```

## Integrating with `django.contrib.sitemaps`

### class `FlatPageSitemap`

The `sitemaps.FlatPageSitemap` class looks at all publicly visible *flatpages* defined for the current `SITE_ID` (see the *sites documentation*) and creates an entry in the sitemap. These entries include only the `location` attribute – not `lastmod`, `changefreq` or `priority`.

### Example

Here's an example of a `URLconf` using `FlatPageSitemap`:

```
from django.conf.urls import url
from django.contrib.flatpages.sitemaps import FlatPageSitemap
from django.contrib.sitemaps.views import sitemap

urlpatterns = [
    # ...

    # the sitemap
    url(r'^sitemap\.xml$', sitemap,
        {'sitemaps': {'flatpages': FlatPageSitemap}},
        name='django.contrib.sitemaps.views.sitemap'),
]
```

## 6.5.5 GeoDjango

GeoDjango intends to be a world-class geographic Web framework. Its goal is to make it as easy as possible to build GIS Web applications and harness the power of spatially enabled data.

### GeoDjango Tutorial

#### Introduction

GeoDjango is an included contrib module for Django that turns it into a world-class geographic Web framework. GeoDjango strives to make it as simple as possible to create geographic Web applications, like location-based services. Its features include:

- Django model fields for [OGC](#) geometries and raster data.
- Extensions to Django's ORM for querying and manipulating spatial data.
- Loosely-coupled, high-level Python interfaces for GIS geometry and raster operations and data manipulation in different formats.
- Editing geometry fields from the admin.

This tutorial assumes familiarity with Django; thus, if you're brand new to Django, please read through the *regular tutorial* to familiarize yourself with Django first.

---

**Note:** GeoDjango has additional requirements beyond what Django requires – please consult the *installation documentation* for more details.

---

This tutorial will guide you through the creation of a geographic web application for viewing the [world borders](#).<sup>1</sup> Some of the code used in this tutorial is taken from and/or inspired by the [GeoDjango basic apps project](#).<sup>2</sup>

---

**Note:** Proceed through the tutorial sections sequentially for step-by-step instructions.

---

## Setting Up

### Create a Spatial Database

Typically no special setup is required, so you can create a database as you would for any other project. We provide some tips for selected databases:

- [Installing PostGIS](#)
- [Installing SpatiaLite](#)

### Create a New Project

Use the standard `django-admin` script to create a project called `geodjango`:

```
$ django-admin startproject geodjango
```

This will initialize a new project. Now, create a world Django application within the `geodjango` project:

```
$ cd geodjango
$ python manage.py startapp world
```

### Configure `settings.py`

The `geodjango` project settings are stored in the `geodjango/settings.py` file. Edit the database connection settings to match your setup:

```
DATABASES = {
    'default': {
        'ENGINE': 'django.contrib.gis.db.backends.postgis',
        'NAME': 'geodjango',
        'USER': 'geo',
    },
}
```

In addition, modify the `INSTALLED_APPS` setting to include `django.contrib.admin`, `django.contrib.gis`, and `world` (your newly created application):

```
INSTALLED_APPS = [
    'django.contrib.admin',
    'django.contrib.auth',
    'django.contrib.contenttypes',
    'django.contrib.sessions',
    'django.contrib.messages',
]
```

---

<sup>1</sup> Special thanks to Bjørn Sandvik of [thematicmapping.org](#) for providing and maintaining this dataset.

<sup>2</sup> GeoDjango basic apps was written by Dane Springmeyer, Josh Livni, and Christopher Schmidt.

```
'django.contrib.staticfiles',
'django.contrib.gis',
'world',
]
```

## Geographic Data

### World Borders

The world borders data is available in this [zip file](#). Create a `data` directory in the `world` application, download the world borders data, and unzip. On GNU/Linux platforms, use the following commands:

```
$ mkdir world/data
$ cd world/data
$ wget http://thematicmapping.org/downloads/TM_WORLD_BORDERS-0.3.zip
$ unzip TM_WORLD_BORDERS-0.3.zip
$ cd ../..
```

The world borders ZIP file contains a set of data files collectively known as an [ESRI Shapefile](#), one of the most popular geospatial data formats. When unzipped, the world borders dataset includes files with the following extensions:

- `.shp`: Holds the vector data for the world borders geometries.
- `.shx`: Spatial index file for geometries stored in the `.shp`.
- `.dbf`: Database file for holding non-geometric attribute data (e.g., integer and character fields).
- `.prj`: Contains the spatial reference information for the geographic data stored in the shapefile.

### Use `ogrinfo` to examine spatial data

The GDAL `ogrinfo` utility allows examining the metadata of shapefiles or other vector data sources:

```
$ ogrinfo world/data/TM_WORLD_BORDERS-0.3.shp
INFO: Open of `world/data/TM_WORLD_BORDERS-0.3.shp'
      using driver `ESRI Shapefile' successful.
1: TM_WORLD_BORDERS-0.3 (Polygon)
```

`ogrinfo` tells us that the shapefile has one layer, and that this layer contains polygon data. To find out more, we'll specify the layer name and use the `-so` option to get only the important summary information:

```
$ ogrinfo -so world/data/TM_WORLD_BORDERS-0.3.shp TM_WORLD_BORDERS-0.3
INFO: Open of `world/data/TM_WORLD_BORDERS-0.3.shp'
      using driver `ESRI Shapefile' successful.

Layer name: TM_WORLD_BORDERS-0.3
Geometry: Polygon
Feature Count: 246
Extent: (-180.000000, -90.000000) - (180.000000, 83.623596)
Layer SRS WKT:
GEOGCS["GCS_WGS_1984",
  DATUM["WGS_1984",
    SPHEROID["WGS_1984", 6378137.0, 298.257223563]],
  PRIMEM["Greenwich", 0.0],
  UNIT["Degree", 0.0174532925199433]]
```

```
FIPS: String (2.0)
ISO2: String (2.0)
ISO3: String (3.0)
UN: Integer (3.0)
NAME: String (50.0)
AREA: Integer (7.0)
POP2005: Integer (10.0)
REGION: Integer (3.0)
SUBREGION: Integer (3.0)
LON: Real (8.3)
LAT: Real (7.3)
```

This detailed summary information tells us the number of features in the layer (246), the geographic bounds of the data, the spatial reference system (“SRS WKT”), as well as type information for each attribute field. For example, `FIPS: String (2.0)` indicates that the FIPS character field has a maximum length of 2. Similarly, `LON: Real (8.3)` is a floating-point field that holds a maximum of 8 digits up to three decimal places.

## Geographic Models

### Defining a Geographic Model

Now that you’ve examined your dataset using `ogrinfo`, create a GeoDjango model to represent this data:

```
from django.contrib.gis.db import models

class WorldBorder(models.Model):
    # Regular Django fields corresponding to the attributes in the
    # world borders shapefile.
    name = models.CharField(max_length=50)
    area = models.IntegerField()
    pop2005 = models.IntegerField('Population 2005')
    fips = models.CharField('FIPS Code', max_length=2)
    iso2 = models.CharField('2 Digit ISO', max_length=2)
    iso3 = models.CharField('3 Digit ISO', max_length=3)
    un = models.IntegerField('United Nations Code')
    region = models.IntegerField('Region Code')
    subregion = models.IntegerField('Sub-Region Code')
    lon = models.FloatField()
    lat = models.FloatField()

    # GeoDjango-specific: a geometry field (MultiPolygonField)
    mpoly = models.MultiPolygonField()

    # Returns the string representation of the model.
    def __str__(self):
        # __unicode__ on Python 2
        return self.name
```

Note that the `models` module is imported from `django.contrib.gis.db`.

The default spatial reference system for geometry fields is WGS84 (meaning the `SRID` is 4326) – in other words, the field coordinates are in longitude, latitude pairs in units of degrees. To use a different coordinate system, set the `SRID` of the geometry field with the `srid` argument. Use an integer representing the coordinate system’s EPSG code.

## Run migrate

After defining your model, you need to sync it with the database. First, create a database migration:

```
$ python manage.py makemigrations
Migrations for 'world':
  world/migrations/0001_initial.py:
    - Create model WorldBorder
```

Let's look at the SQL that will generate the table for the `WorldBorder` model:

```
$ python manage.py sqlmigrate world 0001
```

This command should produce the following output:

```
BEGIN;
--
-- Create model WorldBorder
--
CREATE TABLE "world_worldborder" (
  "id" serial NOT NULL PRIMARY KEY,
  "name" varchar(50) NOT NULL,
  "area" integer NOT NULL,
  "pop2005" integer NOT NULL,
  "fips" varchar(2) NOT NULL,
  "iso2" varchar(2) NOT NULL,
  "iso3" varchar(3) NOT NULL,
  "un" integer NOT NULL,
  "region" integer NOT NULL,
  "subregion" integer NOT NULL,
  "lon" double precision NOT NULL,
  "lat" double precision NOT NULL
  "mpoly" geometry(MULTIPOLYGON,4326) NOT NULL
)
;
CREATE INDEX "world_worldborder_mpoly_id" ON "world_worldborder" USING GIST ( "mpoly"↵
↵);
COMMIT;
```

If this looks correct, run `migrate` to create this table in the database:

```
$ python manage.py migrate
Operations to perform:
  Apply all migrations: admin, auth, contenttypes, sessions, world
Running migrations:
  ...
  Applying world.0001_initial... OK
```

## Importing Spatial Data

This section will show you how to import the world borders shapefile into the database via GeoDjango models using the *LayerMapping data import utility*.

There are many different ways to import data into a spatial database – besides the tools included within GeoDjango, you may also use the following:

- `ogr2ogr`: A command-line utility included with GDAL that can import many vector data formats into PostGIS, MySQL, and Oracle databases.
- `shp2pgsql`: This utility included with PostGIS imports ESRI shapefiles into PostGIS.

## GDAL Interface

Earlier, you used `ogrinfo` to examine the contents of the world borders shapefile. GeoDjango also includes a Pythonic interface to GDAL's powerful OGR library that can work with all the vector data sources that OGR supports.

First, invoke the Django shell:

```
$ python manage.py shell
```

If you downloaded the *World Borders* data earlier in the tutorial, then you can determine its path using Python's built-in `os` module:

```
>>> import os
>>> import world
>>> world_shp = os.path.abspath(os.path.join(os.path.dirname(world.__file__),
...                                         'data', 'TM_WORLD_BORDERS-0.3.shp'))
```

Now, open the world borders shapefile using GeoDjango's *DataSource* interface:

```
>>> from django.contrib.gis.gdal import DataSource
>>> ds = DataSource(world_shp)
>>> print(ds)
/ ... /geodjango/world/data/TM_WORLD_BORDERS-0.3.shp (ESRI Shapefile)
```

Data source objects can have different layers of geospatial features; however, shapefiles are only allowed to have one layer:

```
>>> print(len(ds))
1
>>> lyr = ds[0]
>>> print(lyr)
TM_WORLD_BORDERS-0.3
```

You can see the layer's geometry type and how many features it contains:

```
>>> print(lyr.geom_type)
Polygon
>>> print(len(lyr))
246
```

---

**Note:** Unfortunately, the shapefile data format does not allow for greater specificity with regards to geometry types. This shapefile, like many others, actually includes `MultiPolygon` geometries, not `Polygons`. It's important to use a more general field type in models: a `GeoDjango MultiPolygonField` will accept a `Polygon` geometry, but a `PolygonField` will not accept a `MultiPolygon` type geometry. This is why the `WorldBorder` model defined above uses a `MultiPolygonField`.

---

The *Layer* may also have a spatial reference system associated with it. If it does, the `srs` attribute will return a *SpatialReference* object:

```
>>> srs = lyr.srs
>>> print(srs)
GEOGCS["GCS_WGS_1984",
  DATUM["WGS_1984",
    SPHEROID["WGS_1984",6378137.0,298.257223563]],
  PRIMEM["Greenwich",0.0],
  UNIT["Degree",0.0174532925199433]]
>>> srs.proj4 # PROJ.4 representation
'+proj=longlat +ellps=WGS84 +datum=WGS84 +no_defs '
```

This shapefile is in the popular WGS84 spatial reference system – in other words, the data uses longitude, latitude pairs in units of degrees.

In addition, shapefiles also support attribute fields that may contain additional data. Here are the fields on the World Borders layer:

```
>>> print(lyr.fields)
['FIPS', 'ISO2', 'ISO3', 'UN', 'NAME', 'AREA', 'POP2005', 'REGION', 'SUBREGION', 'LON
↪', 'LAT']
```

The following code will let you examine the OGR types (e.g. integer or string) associated with each of the fields:

```
>>> [fld.__name__ for fld in lyr.field_types]
['OFTString', 'OFTString', 'OFTString', 'OFTInteger', 'OFTString', 'OFTInteger',
↪ 'OFTInteger', 'OFTInteger', 'OFTInteger', 'OFTReal', 'OFTReal']
```

You can iterate over each feature in the layer and extract information from both the feature's geometry (accessed via the `geom` attribute) as well as the feature's attribute fields (whose **values** are accessed via `get()` method):

```
>>> for feat in lyr:
...     print(feat.get('NAME'), feat.geom.num_points)
...
Guernsey 18
Jersey 26
South Georgia South Sandwich Islands 338
Taiwan 363
```

*Layer* objects may be sliced:

```
>>> lyr[0:2]
[<django.contrib.gis.gdal.feature.Feature object at 0x2f47690>, <django.contrib.gis.
↪gdal.feature.Feature object at 0x2f47650>]
```

And individual features may be retrieved by their feature ID:

```
>>> feat = lyr[234]
>>> print(feat.get('NAME'))
San Marino
```

Boundary geometries may be exported as WKT and GeoJSON:

```
>>> geom = feat.geom
>>> print(geom.wkt)
POLYGON ((12.415798 43.957954,12.450554 ...
>>> print(geom.json)
{ "type": "Polygon", "coordinates": [ [ [ 12.415798, 43.957954 ], [ 12.450554, 43.
↪979721 ], ...
```

## LayerMapping

To import the data, use a `LayerMapping` in a Python script. Create a file called `load.py` inside the `world` application, with the following code:

```
import os
from django.contrib.gis.utils import LayerMapping
from .models import WorldBorder

world_mapping = {
    'fips' : 'FIPS',
    'iso2' : 'ISO2',
    'iso3' : 'ISO3',
    'un'   : 'UN',
    'name' : 'NAME',
    'area' : 'AREA',
    'pop2005' : 'POP2005',
    'region' : 'REGION',
    'subregion' : 'SUBREGION',
    'lon' : 'LON',
    'lat' : 'LAT',
    'mpoly' : 'MULTIPOLYGON',
}

world_shp = os.path.abspath(
    os.path.join(os.path.dirname(__file__), 'data', 'TM_WORLD_BORDERS-0.3.shp'),
)

def run(verbose=True):
    lm = LayerMapping(
        WorldBorder, world_shp, world_mapping,
        transform=False, encoding='iso-8859-1',
    )
    lm.save(strict=True, verbose=verbose)
```

A few notes about what's going on:

- Each key in the `world_mapping` dictionary corresponds to a field in the `WorldBorder` model. The value is the name of the shapefile field that data will be loaded from.
- The key `mpoly` for the geometry field is `MULTIPOLYGON`, the geometry type GeoDjango will import the field as. Even simple polygons in the shapefile will automatically be converted into collections prior to insertion into the database.
- The path to the shapefile is not absolute – in other words, if you move the `world` application (with `data` subdirectory) to a different location, the script will still work.
- The `transform` keyword is set to `False` because the data in the shapefile does not need to be converted – it's already in WGS84 (SRID=4326).
- The `encoding` keyword is set to the character encoding of the string values in the shapefile. This ensures that string values are read and saved correctly from their original encoding system.

Afterwards, invoke the Django shell from the `geodjango` project directory:

```
$ python manage.py shell
```

Next, import the `load` module, call the `run` routine, and watch `LayerMapping` do the work:

```
>>> from world import load
>>> load.run()
```

## Try ogrinspect

Now that you've seen how to define geographic models and import data with the *LayerMapping data import utility*, it's possible to further automate this process with use of the *ogrinspect* management command. The *ogrinspect* command introspects a GDAL-supported vector data source (e.g., a shapefile) and generates a model definition and LayerMapping dictionary automatically.

The general usage of the command goes as follows:

```
$ python manage.py ogrinspect [options] <data_source> <model_name> [options]
```

`data_source` is the path to the GDAL-supported data source and `model_name` is the name to use for the model. Command-line options may be used to further define how the model is generated.

For example, the following command nearly reproduces the `WorldBorder` model and mapping dictionary created above, automatically:

```
$ python manage.py ogrinspect world/data/TM_WORLD_BORDERS-0.3.shp WorldBorder \
  --srid=4326 --mapping --multi
```

A few notes about the command-line options given above:

- The `--srid=4326` option sets the SRID for the geographic field.
- The `--mapping` option tells *ogrinspect* to also generate a mapping dictionary for use with *LayerMapping*.
- The `--multi` option is specified so that the geographic field is a *MultiPolygonField* instead of just a *PolygonField*.

The command produces the following output, which may be copied directly into the `models.py` of a GeoDjango application:

```
# This is an auto-generated Django model module created by ogrinspect.
from django.contrib.gis.db import models

class WorldBorder(models.Model):
    fips = models.CharField(max_length=2)
    iso2 = models.CharField(max_length=2)
    iso3 = models.CharField(max_length=3)
    un = models.IntegerField()
    name = models.CharField(max_length=50)
    area = models.IntegerField()
    pop2005 = models.IntegerField()
    region = models.IntegerField()
    subregion = models.IntegerField()
    lon = models.FloatField()
    lat = models.FloatField()
    geom = models.MultiPolygonField(srid=4326)

# Auto-generated `LayerMapping` dictionary for WorldBorder model
worldborders_mapping = {
    'fips' : 'FIPS',
    'iso2' : 'ISO2',
```

```

    'iso3' : 'ISO3',
    'un' : 'UN',
    'name' : 'NAME',
    'area' : 'AREA',
    'pop2005' : 'POP2005',
    'region' : 'REGION',
    'subregion' : 'SUBREGION',
    'lon' : 'LON',
    'lat' : 'LAT',
    'geom' : 'MULTIPOLYGON',
}

```

## Spatial Queries

### Spatial Lookups

GeoDjango adds spatial lookups to the Django ORM. For example, you can find the country in the `WorldBorder` table that contains a particular point. First, fire up the management shell:

```
$ python manage.py shell
```

Now, define a point of interest<sup>3</sup>:

```
>>> pnt_wkt = 'POINT(-95.3385 29.7245)'
```

The `pnt_wkt` string represents the point at -95.3385 degrees longitude, 29.7245 degrees latitude. The geometry is in a format known as Well Known Text (WKT), a standard issued by the Open Geospatial Consortium (OGC).<sup>4</sup> Import the `WorldBorder` model, and perform a `contains` lookup using the `pnt_wkt` as the parameter:

```

>>> from world.models import WorldBorder
>>> WorldBorder.objects.filter(mpoly__contains=pnt_wkt)
<QuerySet [<WorldBorder: United States>]>

```

Here, you retrieved a `QuerySet` with only one model: the border of the United States (exactly what you would expect).

Similarly, you may also use a *GEOS geometry object*. Here, you can combine the `intersects` spatial lookup with the `get` method to retrieve only the `WorldBorder` instance for San Marino instead of a `queryset`:

```

>>> from django.contrib.gis.geos import Point
>>> pnt = Point(12.4604, 43.9420)
>>> WorldBorder.objects.get(mpoly__intersects=pnt)
<WorldBorder: San Marino>

```

The `contains` and `intersects` lookups are just a subset of the available queries – the *GeoDjango Database API* documentation has more.

### Automatic Spatial Transformations

When doing spatial queries, GeoDjango automatically transforms geometries if they're in a different coordinate system. In the following example, coordinates will be expressed in `EPSG SRID 32140`, a coordinate system specific to south Texas **only** and in units of **meters**, not degrees:

<sup>3</sup> This point is the University of Houston Law Center.

<sup>4</sup> Open Geospatial Consortium, Inc., OpenGIS Simple Feature Specification For SQL.

```
>>> from django.contrib.gis.geos import Point, GEOSGeometry
>>> pnt = Point(954158.1, 4215137.1, srid=32140)
```

Note that `pnt` may also be constructed with EWKT, an “extended” form of WKT that includes the SRID:

```
>>> pnt = GEOSGeometry('SRID=32140;POINT(954158.1 4215137.1)')
```

GeoDjango’s ORM will automatically wrap geometry values in transformation SQL, allowing the developer to work at a higher level of abstraction:

```
>>> qs = WorldBorder.objects.filter(mpoly__intersects=pnt)
>>> print(qs.query) # Generating the SQL
SELECT "world_worldborder"."id", "world_worldborder"."name", "world_worldborder"."area
↪",
"world_worldborder"."pop2005", "world_worldborder"."fips", "world_worldborder"."iso2",
"world_worldborder"."iso3", "world_worldborder"."un", "world_worldborder"."region",
"world_worldborder"."subregion", "world_worldborder"."lon", "world_worldborder"."lat",
"world_worldborder"."mpoly" FROM "world_worldborder"
WHERE ST_Intersects("world_worldborder"."mpoly", ST_Transform(%s, 4326))
>>> qs # printing evaluates the queryset
<QuerySet [<WorldBorder: United States>]>
```

## Raw queries

When using *raw queries*, you should generally wrap your geometry fields with the `asText()` SQL function (or `ST_AsText` for PostGIS) so that the field value will be recognized by GEOS:

```
City.objects.raw('SELECT id, name, asText(point) from myapp_city')
```

This is not absolutely required by PostGIS, but generally you should only use raw queries when you know exactly what you are doing.

## Lazy Geometries

GeoDjango loads geometries in a standardized textual representation. When the geometry field is first accessed, GeoDjango creates a *GEOS geometry object* [<ref-geos>](#), exposing powerful functionality, such as serialization properties for popular geospatial formats:

```
>>> sm = WorldBorder.objects.get(name='San Marino')
>>> sm.mpoly
<MultiPolygon object at 0x24c6798>
>>> sm.mpoly.wkt # WKT
MULTIPOLYGON (((12.4157980000000006 43.9579540000000009, 12.4505540000000003 43.
↪ 97972099999999978, ...
>>> sm.mpoly.wkb # WKB (as Python binary buffer)
<read-only buffer for 0x1fe2c70, size -1, offset 0 at 0x2564c40>
>>> sm.mpoly.geojson # GeoJSON (requires GDAL)
{' "type": "MultiPolygon", "coordinates": [ [ [ [ 12.415798, 43.957954 ], [ 12.450554,
↪ 43.979721 ], ...
```

This includes access to all of the advanced geometric operations provided by the GEOS library:

```
>>> pnt = Point(12.4604, 43.9420)
>>> sm.mpoly.contains(pnt)
```

```
True
>>> pnt.contains(sm.mpoly)
False
```

## Geographic annotations

GeoDjango also offers a set of geographic annotations to compute distances and several other operations (intersection, difference, etc.). See the *Geographic Database Functions* documentation.

## Putting your data on the map

### Geographic Admin

GeoDjango extends *Django's admin application* with support for editing geometry fields.

### Basics

GeoDjango also supplements the Django admin by allowing users to create and modify geometries on a JavaScript slippy map (powered by [OpenLayers](#)).

Let's dive right in. Create a file called `admin.py` inside the `world` application with the following code:

```
from django.contrib.gis import admin
from .models import WorldBorder

admin.site.register(WorldBorder, admin.GeoModelAdmin)
```

Next, edit your `urls.py` in the `geodjango` application folder as follows:

```
from django.conf.urls import url, include
from django.contrib.gis import admin

urlpatterns = [
    url(r'^admin/', admin.site.urls),
]
```

Create an admin user:

```
$ python manage.py createsuperuser
```

Next, start up the Django development server:

```
$ python manage.py runserver
```

Finally, browse to `http://localhost:8000/admin/`, and log in with the user you just created. Browse to any of the `WorldBorder` entries – the borders may be edited by clicking on a polygon and dragging the vertexes to the desired position.

## OSMGeoAdmin

With the *OSMGeoAdmin*, GeoDjango uses a [Open Street Map](#) layer in the admin. This provides more context (including street and thoroughfare details) than available with the *GeoModelAdmin* (which uses the [Vector Map Level 0](#) WMS dataset hosted at [OSGeo](#)).

First, there are some important requirements:

- *OSMGeoAdmin* requires that *GDAL* is installed.
- The PROJ.4 datum shifting files must be installed (see the [PROJ.4 installation instructions](#) for more details).

If you meet this requirement, then just substitute the *OSMGeoAdmin* option class in your `admin.py` file:

```
admin.site.register(WorldBorder, admin.OSMGeoAdmin)
```

## GeoDjango Installation

### Overview

In general, GeoDjango installation requires:

1. *Python and Django*
2. *Spatial database*
3. *Installing Geospatial libraries*

Details for each of the requirements and installation instructions are provided in the sections below. In addition, platform-specific instructions are available for:

- *Mac OS X*
- *Windows*

---

### Use the Source

Because GeoDjango takes advantage of the latest in the open source geospatial software technology, recent versions of the libraries are necessary. If binary packages aren't available for your platform, installation from source may be required. When compiling the libraries from source, please follow the directions closely, especially if you're a beginner.

---

## Requirements

### Python and Django

Because GeoDjango is included with Django, please refer to Django's [installation instructions](#) for details on how to install.

### Spatial database

PostgreSQL (with PostGIS), MySQL (mostly with MyISAM engine), Oracle, and SQLite (with SpatialLite) are the spatial databases currently supported.

**Note:** PostGIS is recommended, because it is the most mature and feature-rich open source spatial database.

---

The geospatial libraries required for a GeoDjango installation depends on the spatial database used. The following lists the library requirements, supported versions, and any notes for each of the supported database backends:

Database	Library Requirements	Supported Versions	Notes
PostgreSQL	GEOS, PROJ.4, PostGIS	9.2+	Requires PostGIS.
MySQL	GEOS	5.5+	Not OGC-compliant; <i>limited functionality</i> .
Oracle	GEOS	11.2+	XE not supported.
SQLite	GEOS, GDAL, PROJ.4, SpatiaLite	3.6.+	Requires SpatiaLite 3.0+, pysqlite2 2.5+

See also [this comparison matrix](#) on the OSGeo Wiki for PostgreSQL/PostGIS/GEOS/GDAL possible combinations.

## Installation

### Geospatial libraries

#### Installing Geospatial libraries

GeoDjango uses and/or provides interfaces for the following open source geospatial libraries:

Program	Description	Required	Supported Versions
<i>GEOS</i>	Geometry Engine Open Source	Yes	3.4, 3.3
PROJ.4	Cartographic Projections library	Yes (PostgreSQL and SQLite only)	4.9, 4.8, 4.7, 4.6, 4.5, 4.4
<i>GDAL</i>	Geospatial Data Abstraction Library	Yes (SQLite only)	2.1, 2.0, 1.11, 1.10, 1.9, 1.8, 1.7
<i>GeoIP</i>	IP-based geolocation library	No	2
PostGIS	Spatial extensions for PostgreSQL	Yes (PostgreSQL only)	2.3, 2.2, 2.1, 2.0
Spatialite	Spatial extensions for SQLite	Yes (SQLite only)	4.3, 4.2, 4.1, 4.0, 3.0

Note that older or more recent versions of these libraries *may* also work totally fine with GeoDjango. Your mileage may vary.

---

### Install GDAL

While *GDAL* is technically not required, it is *recommended*. Important features of GeoDjango (including the *LayerMapping data import utility*, geometry reprojection, and the geographic admin) depend on its functionality.

---

**Note:** The GeoDjango interfaces to GEOS, GDAL, and GeoIP may be used independently of Django. In other words, no database or settings file required – just import them as normal from *django.contrib.gis*.

---

On Debian/Ubuntu, you are advised to install the following packages which will install, directly or by dependency, the required geospatial libraries:

```
$ sudo apt-get install binutils libproj-dev gdal-bin
```

Optional packages to consider:

- `libgeoip1`: for *GeoIP* support
- `python-gdal` for GDAL's own Python bindings – includes interfaces for raster manipulation

Please also consult platform-specific instructions if you are on *Mac OS X* or *Windows*.

## Building from source

When installing from source on UNIX and GNU/Linux systems, please follow the installation instructions carefully, and install the libraries in the given order. If using MySQL or Oracle as the spatial database, only GEOS is required.

---

**Note:** On Linux platforms, it may be necessary to run the `ldconfig` command after installing each library. For example:

```
$ sudo make install
$ sudo ldconfig
```

---

**Note:** OS X users are required to install [Apple Developer Tools](#) in order to compile software from source. This is typically included on your OS X installation DVDs.

---

## GEOS

GEOS is a C++ library for performing geometric operations, and is the default internal geometry representation used by GeoDjango (it's behind the “lazy” geometries). Specifically, the C API library is called (e.g., `libgeos_c.so`) directly from Python using `ctypes`.

First, download GEOS 3.4.2 from the GEOS website and untar the source archive:

```
$ wget http://download.osgeo.org/geos/geos-3.4.2.tar.bz2
$ tar xjf geos-3.4.2.tar.bz2
```

Next, change into the directory where GEOS was unpacked, run the configure script, compile, and install:

```
$ cd geos-3.4.2
$ ./configure
$ make
$ sudo make install
$ cd ..
```

## Troubleshooting

### Can't find GEOS library

When GeoDjango can't find GEOS, this error is raised:

```
ImportError: Could not find the GEOS library (tried "geos_c"). Try setting GEOS_
↳LIBRARY_PATH in your settings.
```

The most common solution is to properly configure your *Library environment settings* or set `GEOS_LIBRARY_PATH` in your settings.

If using a binary package of GEOS (e.g., on Ubuntu), you may need to *Install binutils*.

### GEOS\_LIBRARY\_PATH

If your GEOS library is in a non-standard location, or you don't want to modify the system's library path then the `GEOS_LIBRARY_PATH` setting may be added to your Django settings file with the full path to the GEOS C library. For example:

```
GEOS_LIBRARY_PATH = '/home/bob/local/lib/libgeos_c.so'
```

---

**Note:** The setting must be the *full* path to the C shared library; in other words you want to use `libgeos_c.so`, not `libgeos.so`.

---

See also *My logs are filled with GEOS-related errors*.

## PROJ.4

**PROJ.4** is a library for converting geospatial data to different coordinate reference systems.

First, download the PROJ.4 source code and datum shifting files<sup>1</sup>:

```
$ wget http://download.osgeo.org/proj/proj-4.9.1.tar.gz
$ wget http://download.osgeo.org/proj/proj-datumgrid-1.5.tar.gz
```

Next, untar the source code archive, and extract the datum shifting files in the `nad` subdirectory. This must be done *prior* to configuration:

```
$ tar xzf proj-4.9.1.tar.gz
$ cd proj-4.9.1/nad
$ tar xzf ../../proj-datumgrid-1.5.tar.gz
$ cd ..
```

Finally, configure, make and install PROJ.4:

```
$ ./configure
$ make
$ sudo make install
$ cd ..
```

## GDAL

**GDAL** is an excellent open source geospatial library that has support for reading most vector and raster spatial data

---

<sup>1</sup> The datum shifting files are needed for converting data to and from certain projections. For example, the PROJ.4 string for the [Google projection \(900913 or 3857\)](#) requires the `null` grid file only included in the extra datum shifting files. It is easier to install the shifting files now, then to have debug a problem caused by their absence later.

formats. Currently, GeoDjango only supports *GDAL's vector data* capabilities<sup>2</sup>. *GEOS* and *PROJ.4* should be installed prior to building GDAL.

First download the latest GDAL release version and untar the archive:

```
$ wget http://download.osgeo.org/gdal/1.11.2/gdal-1.11.2.tar.gz
$ tar xzf gdal-1.11.2.tar.gz
$ cd gdal-1.11.2
```

Configure, make and install:

```
$ ./configure
$ make # Go get some coffee, this takes a while.
$ sudo make install
$ cd ..
```

---

**Note:** Because GeoDjango has its own Python interface, the preceding instructions do not build GDAL's own Python bindings. The bindings may be built by adding the `--with-python` flag when running `configure`. See [GDAL/OGR In Python](#) for more information on GDAL's bindings.

---

If you have any problems, please see the troubleshooting section below for suggestions and solutions.

## Troubleshooting

### Can't find GDAL library

When GeoDjango can't find the GDAL library, the `HAS_GDAL` flag will be false:

```
>>> from django.contrib.gis import gdal
>>> gdal.HAS_GDAL
False
```

The solution is to properly configure your *Library environment settings* or set `GDAL_LIBRARY_PATH` in your settings.

#### `GDAL_LIBRARY_PATH`

If your GDAL library is in a non-standard location, or you don't want to modify the system's library path then the `GDAL_LIBRARY_PATH` setting may be added to your Django settings file with the full path to the GDAL library. For example:

```
GDAL_LIBRARY_PATH = '/home/sue/local/lib/libgdal.so'
```

## Database installation

### Installing PostGIS

PostGIS adds geographic object support to PostgreSQL, turning it into a spatial database. *GEOS*, *PROJ.4* and *GDAL* should be installed prior to building PostGIS. You might also need additional libraries, see [PostGIS requirements](#).

The `psycopg2` module is required for use as the database adapter when using GeoDjango with PostGIS.

---

<sup>2</sup> Specifically, GeoDjango provides support for the *OGR* library, a component of GDAL.

On Debian/Ubuntu, you are advised to install the following packages: `postgresql-x.x`, `postgresql-x.x-postgis`, `postgresql-server-dev-x.x`, `python-psycopg2` (`x.x` matching the PostgreSQL version you want to install). Alternately, you can [build from source](#). Consult the platform-specific instructions if you are on *Mac OS X* or *Windows*.

## Post-installation

### Creating a spatial database

PostGIS 2 includes an extension for PostgreSQL that's used to enable spatial functionality:

```
$ createdb <db name>
$ psql <db name>
> CREATE EXTENSION postgis;
```

The database user must be a superuser in order to run `CREATE EXTENSION postgis;`. The command is run during the *migrate* process. An alternative is to use a migration operation in your project:

```
from django.contrib.postgres.operations import CreateExtension
from django.db import migrations

class Migration(migrations.Migration):

    operations = [
        CreateExtension('postgis'),
        ...
    ]
```

GeoDjango does not currently leverage any [PostGIS topology functionality](#). If you plan to use those features at some point, you can also install the `postgis_topology` extension by issuing `CREATE EXTENSION postgis_topology;`

### Managing the database

To administer the database, you can either use the pgAdmin III program (*Start* → *PostgreSQL 9.x* → *pgAdmin III*) or the SQL Shell (*Start* → *PostgreSQL 9.x* → *SQL Shell*). For example, to create a `geodjango` spatial database and user, the following may be executed from the SQL Shell as the `postgres` user:

```
postgres# CREATE USER geodjango PASSWORD 'my_passwd';
postgres# CREATE DATABASE geodjango OWNER geodjango;
```

### Installing SpatialLite

[SpatialLite](#) adds spatial support to SQLite, turning it into a full-featured spatial database.

First, check if you can install SpatialLite from system packages or binaries.

For example, on Debian-based distributions, try to install the `spatialite-bin` package. For distributions that package SpatialLite 4.2+, install `libsqlite3-mod-spatialite`.

For Mac OS X, follow the [instructions below](#).

For Windows, you may find binaries on the [Gaia-SINS](#) home page.

In any case, you should always be able to [install from source](#).

**SPATIALITE\_LIBRARY\_PATH** setting required for SpatiaLite 4.2+

If you're using SpatiaLite 4.2+, you must put this in your settings:

```
SPATIALITE_LIBRARY_PATH = 'mod_spatialite'
```

---

## Installing from source

*GEOS* and *PROJ.4* should be installed prior to building SpatiaLite.

## SQLite

Check first if SQLite is compiled with the *R\*Tree* module. Run the `sqlite3` command line interface and enter the following query:

```
sqlite> CREATE VIRTUAL TABLE testrtree USING rtree(id,minX,maxX,minY,maxY);
```

If you obtain an error, you will have to recompile SQLite from source. Otherwise, just skip this section.

To install from sources, download the latest amalgamation source archive from the [SQLite download page](#), and extract:

```
$ wget https://sqlite.org/sqlite-amalgamation-3.6.23.1.tar.gz
$ tar xzf sqlite-amalgamation-3.6.23.1.tar.gz
$ cd sqlite-3.6.23.1
```

Next, run the `configure` script – however the `CFLAGS` environment variable needs to be customized so that SQLite knows to build the *R\*Tree* module:

```
$ CFLAGS="-DSQLITE_ENABLE_RTREE=1" ./configure
$ make
$ sudo make install
$ cd ..
```

## SpatiaLite library (`libspatialite`)

Get the latest SpatiaLite library source bundle from the [download page](#):

```
$ wget http://www.gaia-gis.it/gaia-sins/libspatialite-sources/libspatialite-4.1.0.tar.
→gz
$ tar xaf libspatialite-4.1.0.tar.gz
$ cd libspatialite-4.1.0
$ ./configure
$ make
$ sudo make install
```

**Note:** For Mac OS X users building from source, the SpatiaLite library *and* tools need to have their target configured:

```
$ ./configure --target=macosx
```

---

## Mac OS X-specific instructions

To install the SpatiaLite library and tools, Mac OS X users can choose between *KyngChaos packages* and *Homebrew*.

### KyngChaos

First, follow the instructions in the *KyngChaos packages* section.

When creating a SpatiaLite database, the `spatialite` program is required. However, instead of attempting to compile the SpatiaLite tools from source, download the [SpatiaLite Binaries](#) for OS X, and install `spatialite` in a location available in your `PATH`. For example:

```
$ curl -O http://www.gaia-gis.it/spatialite/spatialite-tools-osx-x86-2.3.1.tar.gz
$ tar xzf spatialite-tools-osx-x86-2.3.1.tar.gz
$ cd spatialite-tools-osx-x86-2.3.1/bin
$ sudo cp spatialite /Library/Frameworks/SQLite3.framework/Programs
```

Finally, for GeoDjango to be able to find the KyngChaos SpatiaLite library, add the following to your `settings.py`:

```
SPATIALITE_LIBRARY_PATH='/Library/Frameworks/SQLite3.framework/SQLite3'
```

### Homebrew

*Homebrew* handles all the SpatiaLite related packages on your behalf, including SQLite3, SpatiaLite, PROJ, and GEOS. Install them like this:

```
$ brew update
$ brew install spatialite-tools
$ brew install gdal
```

Finally, for GeoDjango to be able to find the SpatiaLite library, add the following to your `settings.py`:

```
SPATIALITE_LIBRARY_PATH='/usr/local/lib/mod_spatialite.dylib'
```

### Add `django.contrib.gis` to `INSTALLED_APPS`

Like other Django contrib applications, you will *only* need to add `django.contrib.gis` to `INSTALLED_APPS` in your settings. This is so that the `gis` templates can be located – if not done, then features such as the geographic admin or KML sitemaps will not function properly.

## Troubleshooting

If you can't find the solution to your problem here then participate in the community! You can:

- Join the `#geodjango` IRC channel on Freenode. Please be patient and polite – while you may not get an immediate response, someone will attempt to answer your question as soon as they see it.
- Ask your question on the [GeoDjango mailing list](#).
- File a ticket on the [Django trac](#) if you think there's a bug. Make sure to provide a complete description of the problem, versions used, and specify the component as "GIS".

## Library environment settings

By far, the most common problem when installing GeoDjango is that the external shared libraries (e.g., for GEOS and GDAL) cannot be located.<sup>1</sup> Typically, the cause of this problem is that the operating system isn't aware of the directory where the libraries built from source were installed.

In general, the library path may be set on a per-user basis by setting an environment variable, or by configuring the library path for the entire system.

### LD\_LIBRARY\_PATH environment variable

A user may set this environment variable to customize the library paths they want to use. The typical library directory for software built from source is `/usr/local/lib`. Thus, `/usr/local/lib` needs to be included in the `LD_LIBRARY_PATH` variable. For example, the user could place the following in their bash profile:

```
export LD_LIBRARY_PATH=/usr/local/lib
```

### Setting system library path

On GNU/Linux systems, there is typically a file in `/etc/ld.so.conf`, which may include additional paths from files in another directory, such as `/etc/ld.so.conf.d`. As the root user, add the custom library path (like `/usr/local/lib`) on a new line in `ld.so.conf`. This is *one* example of how to do so:

```
$ sudo echo /usr/local/lib >> /etc/ld.so.conf
$ sudo ldconfig
```

For OpenSolaris users, the system library path may be modified using the `crle` utility. Run `crle` with no options to see the current configuration and use `crle -l` to set with the new library path. Be *very* careful when modifying the system library path:

```
# crle -l $OLD_PATH:/usr/local/lib
```

### Install binutils

GeoDjango uses the `find_library` function (from the `ctypes.util` Python module) to discover libraries. The `find_library` routine uses a program called `objdump` (part of the `binutils` package) to verify a shared library on GNU/Linux systems. Thus, if `binutils` is not installed on your Linux system then Python's `ctypes` may not be able to find your library even if your library path is set correctly and geospatial libraries were built perfectly.

The `binutils` package may be installed on Debian and Ubuntu systems using the following command:

```
$ sudo apt-get install binutils
```

Similarly, on Red Hat and CentOS systems:

```
$ sudo yum install binutils
```

---

<sup>1</sup> GeoDjango uses the `find_library()` routine from `ctypes.util` to locate shared libraries.

## Platform-specific instructions

### Mac OS X

Because of the variety of packaging systems available for OS X, users have several different options for installing GeoDjango. These options are:

- *Postgres.app* (easiest and recommended)
- *Homebrew*
- *KyngChaos packages*
- *Fink*
- *MacPorts*
- *Building from source*

This section also includes instructions for installing an upgraded version of *Python* from packages provided by the Python Software Foundation, however, this is not required.

### Python

Although OS X comes with Python installed, users can use [framework installers](#) provided by the Python Software Foundation. An advantage to using the installer is that OS X's Python will remain “pristine” for internal operating system use.

---

**Note:** You will need to modify the `PATH` environment variable in your `.profile` file so that the new version of Python is used when `python` is entered at the command-line:

```
export PATH=/Library/Frameworks/Python.framework/Versions/Current/bin:$PATH
```

---

### Postgres.app

*Postgres.app* is a standalone PostgreSQL server that includes the PostGIS extension. You will also need to install `gdal` and `libgeopip` with *Homebrew*.

After installing *Postgres.app*, add the following to your `.bash_profile` so you can run the package's programs from the command-line. Replace `X.Y` with the version of PostgreSQL in the *Postgres.app* you installed:

```
export PATH=$PATH:/Applications/Postgres.app/Contents/Versions/X.Y/bin
```

You can check if the path is set up correctly by typing `which psql` at a terminal prompt.

### Homebrew

*Homebrew* provides “recipes” for building binaries and packages from source. It provides recipes for the GeoDjango prerequisites on Macintosh computers running OS X. Because Homebrew still builds the software from source, the [Apple Developer Tools](#) are required.

Summary:

```
$ brew install postgresql
$ brew install postgis
$ brew install gdal
$ brew install libgeoip
```

## KyngChaos packages

William Kyngesburye provides a number of [geospatial library binary packages](#) that make it simple to get GeoDjango installed on OS X without compiling them from source. However, the [Apple Developer Tools](#) are still necessary for compiling the Python database adapters *psycpg2* (for PostGIS) and *pysqlite2* (for SpatiaLite).

---

**Note:** SpatiaLite users should consult the *Mac OS X-specific instructions* section after installing the packages for additional instructions.

---

Download the framework packages for:

- UnixImageIO
- PROJ
- GEOS
- SQLite3 (includes the SpatiaLite library)
- GDAL

Install the packages in the order they are listed above, as the GDAL and SQLite packages require the packages listed before them.

Afterwards, you can also install the KyngChaos binary packages for [PostgreSQL](#) and [PostGIS](#).

After installing the binary packages, you'll want to add the following to your `.profile` to be able to run the package programs from the command-line:

```
export PATH=/Library/Frameworks/UnixImageIO.framework/Programs:$PATH
export PATH=/Library/Frameworks/PROJ.framework/Programs:$PATH
export PATH=/Library/Frameworks/GEOS.framework/Programs:$PATH
export PATH=/Library/Frameworks/SQLite3.framework/Programs:$PATH
export PATH=/Library/Frameworks/GDAL.framework/Programs:$PATH
export PATH=/usr/local/pgsql/bin:$PATH
```

## psycpg2

After you've installed the KyngChaos binaries and modified your `PATH`, as described above, *psycpg2* may be installed using the following command:

```
$ pip install psycpg2
```

---

**Note:** If you don't have `pip`, follow the *installation instructions* to install it.

---

## Fink

Kurt Schwehr has been gracious enough to create GeoDjango packages for users of the [Fink](#) package system. [Different packages are available](#) (starting with `django-gis`), depending on which version of Python you want to use.

## MacPorts

[MacPorts](#) may be used to install GeoDjango prerequisites on Macintosh computers running OS X. Because MacPorts still builds the software from source, the [Apple Developer Tools](#) are required.

Summary:

```
$ sudo port install postgresql93-server
$ sudo port install geos
$ sudo port install proj
$ sudo port install postgis
$ sudo port install gdal +geos
$ sudo port install libgeopip
```

---

**Note:** You will also have to modify the `PATH` in your `.profile` so that the MacPorts programs are accessible from the command-line:

```
export PATH=/opt/local/bin:/opt/local/lib/postgresql93/bin
```

In addition, add the `DYLD_FALLBACK_LIBRARY_PATH` setting so that the libraries can be found by Python:

```
export DYLD_FALLBACK_LIBRARY_PATH=/opt/local/lib:/opt/local/lib/postgresql93
```

---

## Windows

Proceed through the following sections sequentially in order to install GeoDjango on Windows.

### Python

*Install Python.*

### PostgreSQL

First, download the latest [PostgreSQL 9.x installer](#) from the [EnterpriseDB](#) website. After downloading, simply run the installer, follow the on-screen directions, and keep the default options unless you know the consequences of changing them.

---

**Note:** The PostgreSQL installer creates both a new Windows user to be the ‘postgres service account’ and a `postgres` database superuser. You will be prompted once to set the password for both accounts – make sure to remember it!

---

When the installer completes, it will ask to launch the Application Stack Builder (ASB) on exit – keep this checked, as it is necessary to install *PostGIS*.

---

**Note:** If installed successfully, the PostgreSQL server will run in the background each time the system is started as a Windows service. A *PostgreSQL 9.x* start menu group will be created and contains shortcuts for the ASB as well as the ‘SQL Shell’, which will launch a `psql` command window.

---

## PostGIS

From within the Application Stack Builder (to run outside of the installer, *Start* → *Programs* → *PostgreSQL 9.x*), select *PostgreSQL Database Server 9.x on port 5432* from the drop down menu. Next, expand the *Categories* → *Spatial Extensions* menu tree and select *PostGIS X.Y for PostgreSQL 9.x*.

After clicking next, you will be prompted to select your mirror, PostGIS will be downloaded, and the PostGIS installer will begin. Select only the default options during install (e.g., do not uncheck the option to create a default PostGIS database).

---

**Note:** You will be prompted to enter your `postgres` database superuser password in the ‘Database Connection Information’ dialog.

---

## psycopg2

The `psycopg2` Python module provides the interface between Python and the PostgreSQL database. Download the latest [Windows installer](#) for your version of Python and PostgreSQL and run using the default settings.<sup>2</sup>

## OSGeo4W

The *OSGeo4W installer* makes it simple to install the PROJ.4, GDAL, and GEOS libraries required by GeoDjango. First, download the *OSGeo4W installer*, and run it. Select *Express Web-GIS Install* and click next. In the ‘Select Packages’ list, ensure that GDAL is selected; MapServer and Apache are also enabled by default, but are not required by GeoDjango and may be unchecked safely. After clicking next, the packages will be automatically downloaded and installed, after which you may exit the installer.

## Modify Windows environment

In order to use GeoDjango, you will need to add your Python and OSGeo4W directories to your Windows system Path, as well as create `GDAL_DATA` and `PROJ_LIB` environment variables. The following set of commands, executable with `cmd.exe`, will set this up:

```
set OSGEO4W_ROOT=C:\OSGeo4W
set PYTHON_ROOT=C:\Python27
set GDAL_DATA=%OSGEO4W_ROOT%\share\gdal
set PROJ_LIB=%OSGEO4W_ROOT%\share\proj
set PATH=%PATH%;%PYTHON_ROOT%;%OSGEO4W_ROOT%\bin
reg ADD "HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Environment" /v Path /
↪t REG_EXPAND_SZ /f /d "%PATH%"
reg ADD "HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Environment" /v GDAL_
↪DATA /t REG_EXPAND_SZ /f /d "%GDAL_DATA%"
reg ADD "HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Environment" /v PROJ_
↪LIB /t REG_EXPAND_SZ /f /d "%PROJ_LIB%"
```

<sup>2</sup> The `psycopg2` Windows installers are packaged and maintained by Jason Erickson.

---

For your convenience, these commands are available in the executable batch script, `geodjango_setup.bat`.

---

**Note:** Administrator privileges are required to execute these commands. To do this, right-click on `geodjango_setup.bat` and select *Run as administrator*. You need to log out and log back in again for the settings to take effect.

---

---

**Note:** If you customized the Python or OSGeo4W installation directories, then you will need to modify the `OSGEO4W_ROOT` and/or `PYTHON_ROOT` variables accordingly.

---

## Install Django and set up database

Finally, *install Django* on your system.

## GeoDjango Model API

This document explores the details of the GeoDjango Model API. Throughout this section, we'll be using the following geographic model of a [ZIP code](#) and of a [Digital Elevation Model](#) as our examples:

```
from django.contrib.gis.db import models

class Zipcode(models.Model):
    code = models.CharField(max_length=5)
    poly = models.PolygonField()

class Elevation(models.Model):
    name = models.CharField(max_length=100)
    rast = models.RasterField()
```

## Spatial Field Types

Spatial fields consist of a series of geometry field types and one raster field type. Each of the geometry field types correspond to the OpenGIS Simple Features specification<sup>1</sup>. There is no such standard for raster data.

### GeometryField

```
class GeometryField
```

### PointField

```
class PointField
```

---

<sup>1</sup> OpenGIS Consortium, Inc., Simple Feature Specification For SQL.

**LineStringField**

```
class LineStringField
```

**PolygonField**

```
class PolygonField
```

**MultiPointField**

```
class MultiPointField
```

**MultiLineStringField**

```
class MultiLineStringField
```

**MultiPolygonField**

```
class MultiPolygonField
```

**GeometryCollectionField**

```
class GeometryCollectionField
```

**RasterField**

```
class RasterField
```

`RasterField` is currently only implemented for the PostGIS backend.

## Spatial Field Options

The geometry field options `srid` and `spatial_index` are now shared by `GeometryField` and `RasterField` through the `BaseSpatialField`.

In addition to the regular *Field options* available for Django model fields, spatial fields have the following additional options. All are optional.

**srid**

`BaseSpatialField.srid`

Sets the SRID<sup>2</sup> (Spatial Reference System Identity) of the geometry field to the given value. Defaults to 4326 (also known as [WGS84](#), units are in degrees of longitude and latitude).

---

<sup>2</sup> See *id.* at Ch. 2.3.8, p. 39 (Geometry Values and Spatial Reference Systems).

## Selecting an SRID

Choosing an appropriate SRID for your model is an important decision that the developer should consider carefully. The SRID is an integer specifier that corresponds to the projection system that will be used to interpret the data in the spatial database.<sup>3</sup> Projection systems give the context to the coordinates that specify a location. Although the details of *geodesy* are beyond the scope of this documentation, the general problem is that the earth is spherical and representations of the earth (e.g., paper maps, Web maps) are not.

Most people are familiar with using latitude and longitude to reference a location on the earth's surface. However, latitude and longitude are angles, not distances. In other words, while the shortest path between two points on a flat surface is a straight line, the shortest path between two points on a curved surface (such as the earth) is an *arc* of a *great circle*.<sup>4</sup> Thus, additional computation is required to obtain distances in planar units (e.g., kilometers and miles). Using a geographic coordinate system may introduce complications for the developer later on. For example, SpatialLite does not have the capability to perform distance calculations between geometries using geographic coordinate systems, e.g. constructing a query to find all points within 5 miles of a county boundary stored as WGS84.<sup>5</sup>

Portions of the earth's surface may be projected onto a two-dimensional, or Cartesian, plane. Projected coordinate systems are especially convenient for region-specific applications, e.g., if you know that your database will only cover geometries in *North Kansas*, then you may consider using a projection system specific to that region. Moreover, projected coordinate systems are defined in Cartesian units (such as meters or feet), easing distance calculations.

---

**Note:** If you wish to perform arbitrary distance queries using non-point geometries in WGS84 in PostGIS and you want decent performance, enable the `GeometryField.geography` keyword so that *geography database type* is used instead.

---

Additional Resources:

- [spatialreference.org](http://spatialreference.org): A Django-powered database of spatial reference systems.
- [The State Plane Coordinate System](#): A website covering the various projection systems used in the United States. Much of the U.S. spatial data encountered will be in one of these coordinate systems rather than in a geographic coordinate system such as WGS84.

## `spatial_index`

`BaseSpatialField.spatial_index`

Defaults to `True`. Creates a spatial index for the given geometry field.

---

**Note:** This is different from the `db_index` field option because spatial indexes are created in a different manner than regular database indexes. Specifically, spatial indexes are typically created using a variant of the R-Tree, while regular database indexes typically use B-Trees.

---

## Geometry Field Options

There are additional options available for Geometry fields. All the following options are optional.

---

<sup>3</sup> Typically, SRID integer corresponds to an EPSG (European Petroleum Survey Group) identifier. However, it may also be associated with custom projections defined in spatial database's spatial reference systems table.

<sup>4</sup> Terry A. Slocum, Robert B. McMaster, Fritz C. Kessler, & Hugh H. Howard, *Thematic Cartography and Geographic Visualization* (Prentice Hall, 2nd edition), at Ch. 7.1.3.

<sup>5</sup> This limitation does not apply to PostGIS.

## dim

GeometryField.**dim**

This option may be used for customizing the coordinate dimension of the geometry field. By default, it is set to 2, for representing two-dimensional geometries. For spatial backends that support it, it may be set to 3 for three-dimensional support.

---

**Note:** At this time 3D support is limited to the PostGIS spatial backend.

---

## geography

GeometryField.**geography**

If set to `True`, this option will create a database column of type geography, rather than geometry. Please refer to the *geography type* section below for more details.

---

**Note:** Geography support is limited to PostGIS and will force the SRID to be 4326.

---

## Geography Type

The geography type provides native support for spatial features represented with geographic coordinates (e.g., WGS84 longitude/latitude).<sup>6</sup> Unlike the plane used by a geometry type, the geography type uses a spherical representation of its data. Distance and measurement operations performed on a geography column automatically employ great circle arc calculations and return linear units. In other words, when `ST_Distance` is called on two geographies, a value in meters is returned (as opposed to degrees if called on a geometry column in WGS84).

Because geography calculations involve more mathematics, only a subset of the PostGIS spatial lookups are available for the geography type. Practically, this means that in addition to the *distance lookups* only the following additional *spatial lookups* are available for geography columns:

- *bboverlaps*
- *coveredby*
- *covers*
- *intersects*

If you need to use a spatial lookup or aggregate that doesn't support the geography type as input, you can use the `Cast` database function to convert the geography column to a geometry type in the query:

```
from django.contrib.gis.db.models import PointField
from django.db.models.functions import Cast

Zipcode.objects.annotate(
    geom=Cast('geography_field', PointField())
).filter(geom__within=poly)
```

For more information, the PostGIS documentation contains a helpful section on determining *when to use geography data type over geometry data type*.

---

<sup>6</sup> Please refer to the PostGIS Geography Type documentation for more details.

## GeoManager

### class GeoManager

The `GeoManager` is required in order to use the legacy *GeoQuerySet Methods*.

Deprecated since version 1.9: All `GeoQuerySet` methods have been deprecated and replaced by *equivalent database functions*. As soon as the legacy methods have been replaced in your code, you should be able to remove the special `GeoManager` from your GIS-enabled classes.

In older versions, the manager was required to conduct geographic queries. Without it, all geographic filters failed.

`GeoManager` was required even if the model did not have a geographic field itself, e.g., in the case of a `ForeignKey` relation to a model with a geographic field. For example, if we had an `Address` model with a `ForeignKey` to our `Zipcode` model:

```
from django.contrib.gis.db import models

class Address(models.Model):
    num = models.IntegerField()
    street = models.CharField(max_length=100)
    city = models.CharField(max_length=100)
    state = models.CharField(max_length=2)
    zipcode = models.ForeignKey(Zipcode, on_delete=models.CASCADE)
    objects = models.GeoManager()
```

The geographic manager was needed to do spatial queries on related `Zipcode` objects, for example:

```
qs = Address.objects.filter(zipcode__poly__contains='POINT(-104.590948 38.319914)')
```

## GeoDjango Database API

### Spatial Backends

GeoDjango currently provides the following spatial database backends:

- `django.contrib.gis.db.backends.postgis`
- `django.contrib.gis.db.backends.mysql`
- `django.contrib.gis.db.backends.oracle`
- `django.contrib.gis.db.backends.spatialite`

### MySQL Spatial Limitations

MySQL's spatial extensions only support bounding box operations (what MySQL calls minimum bounding rectangles, or MBR). Specifically, [MySQL does not conform to the OGC standard](#):

Currently, MySQL does not implement these functions [`Contains`, `Crosses`, `Disjoint`, `Intersects`, `Overlaps`, `Touches`, `Within`] according to the specification. Those that are implemented return the same result as the corresponding MBR-based functions.

In other words, while spatial lookups such as `contains` are available in GeoDjango when using MySQL, the results returned are really equivalent to what would be returned when using `bbcontains` on a different spatial backend.

**Warning:** True spatial indexes (R-trees) are only supported with MyISAM tables on MySQL.<sup>5</sup> In other words, when using MySQL spatial extensions you have to choose between fast spatial lookups and the integrity of your data – MyISAM tables do not support transactions or foreign key constraints.

## Raster Support

`RasterField` is currently only implemented for the PostGIS backend. Spatial lookups are available for raster fields, but spatial database functions and aggregates aren't implemented for raster fields.

`RasterField` now supports spatial lookups.

## Creating and Saving Models with Geometry Fields

Here is an example of how to create a geometry object (assuming the `Zipcode` model):

```
>>> from zipcode.models import Zipcode
>>> z = Zipcode(code=77096, poly='POLYGON(( 10 10, 10 20, 20 20, 20 15, 10 10))')
>>> z.save()
```

`GEOSGeometry` objects may also be used to save geometric models:

```
>>> from django.contrib.gis.geos import GEOSGeometry
>>> poly = GEOSGeometry('POLYGON(( 10 10, 10 20, 20 20, 20 15, 10 10))')
>>> z = Zipcode(code=77096, poly=poly)
>>> z.save()
```

Moreover, if the `GEOSGeometry` is in a different coordinate system (has a different SRID value) than that of the field, then it will be implicitly transformed into the SRID of the model's field, using the spatial database's transform procedure:

```
>>> poly_3084 = GEOSGeometry('POLYGON(( 10 10, 10 20, 20 20, 20 15, 10 10))',
↳srid=3084) # SRID 3084 is 'NAD83(HARN) / Texas Centric Lambert Conformal'
>>> z = Zipcode(code=78212, poly=poly_3084)
>>> z.save()
>>> from django.db import connection
>>> print(connection.queries[-1]['sql']) # printing the last SQL statement executed
↳(requires DEBUG=True)
INSERT INTO "geoapp_zipcode" ("code", "poly") VALUES (78212, ST_Transform(ST_
↳GeomFromWKB('\001 ... ', 3084), 4326))
```

Thus, geometry parameters may be passed in using the `GEOSGeometry` object, WKT (Well Known Text<sup>1</sup>), HEXEWKB (PostGIS specific – a WKB geometry in hexadecimal<sup>2</sup>), and GeoJSON<sup>3</sup> (requires GDAL). Essentially, if the input is not a `GEOSGeometry` object, the geometry field will attempt to create a `GEOSGeometry` instance from the input.

<sup>5</sup> See [Creating Spatial Indexes in the MySQL Reference Manual](#):

For MyISAM tables, `SPATIAL INDEX` creates an R-tree index. For storage engines that support nonspatial indexing of spatial columns, the engine creates a B-tree index. A B-tree index on spatial values will be useful for exact-value lookups, but not for range scans.

<sup>1</sup> See [Open Geospatial Consortium, Inc., OpenGIS Simple Feature Specification For SQL](#), Document 99-049 (May 5, 1999), at Ch. 3.2.5, p. 3-11 (SQL Textual Representation of Geometry).

<sup>2</sup> See [PostGIS EWKB, EWKT and Canonical Forms](#), PostGIS documentation at Ch. 4.1.2.

<sup>3</sup> See [Howard Butler, Martin Daly, Allan Doyle, Tim Schaub, & Christopher Schmidt, The GeoJSON Format Specification, Revision 1.0](#) (June 16, 2008).

For more information creating *GEOSGeometry* objects, refer to the *GEOS tutorial*.

## Creating and Saving Models with Raster Fields

When creating raster models, the raster field will implicitly convert the input into a *GDALRaster* using lazy-evaluation. The raster field will therefore accept any input that is accepted by the *GDALRaster* constructor.

Here is an example of how to create a raster object from a raster file `volcano.tif` (assuming the Elevation model):

```
>>> from elevation.models import Elevation
>>> dem = Elevation(name='Volcano', rast='/path/to/raster/volcano.tif')
>>> dem.save()
```

*GDALRaster* objects may also be used to save raster models:

```
>>> from django.contrib.gis.gdal import GDALRaster
>>> rast = GDALRaster({'width': 10, 'height': 10, 'name': 'Canyon', 'srid': 4326,
...                   'scale': [0.1, -0.1], 'bands': [{"data": range(100)}]})
>>> dem = Elevation(name='Canyon', rast=rast)
>>> dem.save()
```

Note that this equivalent to:

```
>>> dem = Elevation.objects.create(
...     name='Canyon',
...     rast={'width': 10, 'height': 10, 'name': 'Canyon', 'srid': 4326,
...           'scale': [0.1, -0.1], 'bands': [{"data": range(100)}]},
... )
```

## Spatial Lookups

GeoDjango's lookup types may be used with any manager method like `filter()`, `exclude()`, etc. However, the lookup types unique to GeoDjango are only available on spatial fields.

Filters on 'normal' fields (e.g. *CharField*) may be chained with those on geographic fields. Geographic lookups accept geometry and raster input on both sides and input types can be mixed freely.

The general structure of geographic lookups is described below. A complete reference can be found in the *spatial lookup reference*.

## Geometry Lookups

Geographic queries with geometries take the following general form (assuming the `Zipcode` model used in the *GeoDjango Model API*):

```
>>> qs = Zipcode.objects.filter(<field>__<lookup_type>=<parameter>)
>>> qs = Zipcode.objects.exclude(...)
```

For example:

```
>>> qs = Zipcode.objects.filter(poly__contains=pnt)
>>> qs = Elevation.objects.filter(poly__contains=rst)
```

In this case, `poly` is the geographic field, `contains` is the spatial lookup type, `pnt` is the parameter (which may be a `GEOSGeometry` object or a string of GeoJSON, WKT, or HEXEWKB), and `rst` is a `GDALRaster` object.

## Raster Lookups

The raster lookup syntax is similar to the syntax for geometries. The only difference is that a band index can be specified as additional input. If no band index is specified, the first band is used by default (index 0). In that case the syntax is identical to the syntax for geometry lookups.

To specify the band index, an additional parameter can be specified on both sides of the lookup. On the left hand side, the double underscore syntax is used to pass a band index. On the right hand side, a tuple of the raster and band index can be specified.

This results in the following general form for lookups involving rasters (assuming the `Elevation` model used in the *GeoDjango Model API*):

```
>>> qs = Elevation.objects.filter(<field>__<lookup_type>=<parameter>)
>>> qs = Elevation.objects.filter(<field>__<band_index>__<lookup_type>=<parameter>)
>>> qs = Elevation.objects.filter(<field>__<lookup_type>=(<raster_input, <band_index>))
```

For example:

```
>>> qs = Elevation.objects.filter(rast__contains=geom)
>>> qs = Elevation.objects.filter(rast__contains=rst)
>>> qs = Elevation.objects.filter(rast__1__contains=geom)
>>> qs = Elevation.objects.filter(rast__contains=(rst, 1))
>>> qs = Elevation.objects.filter(rast__1__contains=(rst, 1))
```

On the left hand side of the example, `rast` is the geographic raster field and `contains` is the spatial lookup type. On the right hand side, `geom` is a geometry input and `rst` is a `GDALRaster` object. The band index defaults to 0 in the first two queries and is set to 1 on the others.

While all spatial lookups can be used with raster objects on both sides, not all underlying operators natively accept raster input. For cases where the operator expects geometry input, the raster is automatically converted to a geometry. It's important to keep this in mind when interpreting the lookup results.

The type of raster support is listed for all lookups in the *compatibility table*. Lookups involving rasters are currently only available for the PostGIS backend.

## Distance Queries

### Introduction

Distance calculations with spatial data is tricky because, unfortunately, the Earth is not flat. Some distance queries with fields in a geographic coordinate system may have to be expressed differently because of limitations in PostGIS. Please see the *Selecting an SRID* section in the *GeoDjango Model API* documentation for more details.

### Distance Lookups

*Availability:* PostGIS, Oracle, SpatiaLite, PGRaster (Native)

The following distance lookups are available:

- `distance_lt`

- `distance_lte`
- `distance_gt`
- `distance_gte`
- `dwithin`

---

**Note:** For *measuring*, rather than querying on distances, use the `Distance` function.

---

Distance lookups take a tuple parameter comprising:

1. A geometry or raster to base calculations from; and
2. A number or `Distance` object containing the distance.

If a `Distance` object is used, it may be expressed in any units (the SQL generated will use units converted to those of the field); otherwise, numeric parameters are assumed to be in the units of the field.

---

**Note:** In PostGIS, `ST_Distance_Sphere` does *not* limit the geometry types geographic distance queries are performed with.<sup>4</sup> However, these queries may take a long time, as great-circle distances must be calculated on the fly for *every* row in the query. This is because the spatial index on traditional geometry fields cannot be used.

For much better performance on WGS84 distance queries, consider using *geography columns* in your database instead because they are able to use their spatial index in distance queries. You can tell GeoDjango to use a geography column by setting `geography=True` in your field definition.

---

For example, let's say we have a `SouthTexasCity` model (from the [GeoDjango distance tests](#) ) on a *projected* coordinate system valid for cities in southern Texas:

```
from django.contrib.gis.db import models

class SouthTexasCity(models.Model):
    name = models.CharField(max_length=30)
    # A projected coordinate system (only valid for South Texas!)
    # is used, units are in meters.
    point = models.PointField(srid=32140)
```

Then distance queries may be performed as follows:

```
>>> from django.contrib.gis.geos import GEOSGeometry
>>> from django.contrib.gis.measure import D # ``D`` is a shortcut for ``Distance``
>>> from geoapp.models import SouthTexasCity
# Distances will be calculated from this point, which does not have to be projected.
>>> pnt = GEOSGeometry('POINT(-96.876369 29.905320)', srid=4326)
# If numeric parameter, units of field (meters in this case) are assumed.
>>> qs = SouthTexasCity.objects.filter(point__distance_lte=(pnt, 7000))
# Find all Cities within 7 km, > 20 miles away, and > 100 chains away (an obscure_
↪unit)
>>> qs = SouthTexasCity.objects.filter(point__distance_lte=(pnt, D(km=7)))
>>> qs = SouthTexasCity.objects.filter(point__distance_gte=(pnt, D(mi=20)))
>>> qs = SouthTexasCity.objects.filter(point__distance_gte=(pnt, D(chain=100)))
```

Raster queries work the same way by simply replacing the geometry field `point` with a raster field, or the `pnt` object with a raster object, or both. To specify the band index of a raster input on the right hand side, a 3-tuple can be passed to the lookup as follows:

---

<sup>4</sup> See PostGIS documentation on `ST_DistanceSphere`.

```
>>> qs = SouthTexasCity.objects.filter(point__distance_gte=(rst, 2, D(km=7)))
```

Where the band with index 2 (the third band) of the raster `rst` would be used for the lookup.

## Compatibility Tables

### Spatial Lookups

The following table provides a summary of what spatial lookups are available for each spatial database backend. The PostGIS Raster (PGRaster) lookups are divided into the three categories described in the *raster lookup details*: native support N, bilateral native support B, and geometry conversion support C.

Lookup Type	PostGIS	Oracle	MySQL <sup>6</sup>	Spatialite	PGRaster
<i>bbcontains</i>	X		X	X	N
<i>bboverlaps</i>	X		X	X	N
<i>contained</i>	X		X	X	N
<i>contains</i>	X	X	X	X	B
<i>contains_properly</i>	X				B
<i>coveredby</i>	X	X			B
<i>covers</i>	X	X			B
<i>crosses</i>	X			X	C
<i>disjoint</i>	X	X	X	X	B
<i>distance_gt</i>	X	X		X	N
<i>distance_gte</i>	X	X		X	N
<i>distance_lt</i>	X	X		X	N
<i>distance_lte</i>	X	X		X	N
<i>dwithin</i>	X	X			B
<i>equals</i>	X	X	X	X	C
<i>exact</i>	X	X	X	X	B
<i>intersects</i>	X	X	X	X	B
<i>isvalid</i>	X				
<i>overlaps</i>	X	X	X	X	B
<i>relate</i>	X	X		X	C
<i>same_as</i>	X	X	X	X	B
<i>touches</i>	X	X	X	X	B
<i>within</i>	X	X	X	X	B
<i>left</i>	X				C
<i>right</i>	X				C
<i>overlaps_left</i>	X				B
<i>overlaps_right</i>	X				B
<i>overlaps_above</i>	X				C
<i>overlaps_below</i>	X				C
<i>strictly_above</i>	X				C
<i>strictly_below</i>	X				C

<sup>6</sup> Refer *MySQL Spatial Limitations* section for more details.

## Database functions

The following table provides a summary of what geography-specific database functions are available on each spatial backend.

Function	PostGIS	Oracle	MySQL	SpatialLite
<i>Area</i>	X	X	X	X
<i>AsGeoJSON</i>	X			X
<i>AsGML</i>	X			X
<i>AsKML</i>	X			X
<i>AsSVG</i>	X			X
<i>BoundingBox</i>	X			
<i>Centroid</i>	X	X	X	X
<i>Difference</i>	X	X	X ( $\geq 5.6.1$ )	X
<i>Distance</i>	X	X	X ( $\geq 5.6.1$ )	X
<i>Envelope</i>	X		X	X
<i>ForceRHR</i>	X			
<i>GeoHash</i>	X			X ( $\geq 4.0$ , LWGEOM)
<i>Intersection</i>	X	X	X ( $\geq 5.6.1$ )	X
<i>IsValid</i>	X			
<i>Length</i>	X	X	X	X
<i>MakeValid</i>	X			
<i>MemSize</i>	X			
<i>NumGeometries</i>	X	X	X	X
<i>NumPoints</i>	X	X	X	X
<i>Perimeter</i>	X	X		X ( $\geq 4.0$ )
<i>PointOnSurface</i>	X	X		X
<i>Reverse</i>	X	X		X ( $\geq 4.0$ )
<i>Scale</i>	X			X
<i>SnapToGrid</i>	X			X ( $\geq 3.1$ )
<i>SymDifference</i>	X	X	X ( $\geq 5.6.1$ )	X
<i>Transform</i>	X	X		X
<i>Translate</i>	X			X
<i>Union</i>	X	X	X ( $\geq 5.6.1$ )	X

## Aggregate Functions

The following table provides a summary of what GIS-specific aggregate functions are available on each spatial backend. Please note that MySQL does not support any of these aggregates, and is thus excluded from the table.

Aggregate	PostGIS	Oracle	SpatialLite
<i>Collect</i>	X		X
<i>Extent</i>	X	X	X
<i>Extent3D</i>	X		
<i>MakeLine</i>	X		X
<i>Union</i>	X	X	X

## GeoDjango Forms API

GeoDjango provides some specialized form fields and widgets in order to visually display and edit geolocalized data on a map. By default, they use [OpenLayers](#)-powered maps, with a base WMS layer provided by [Metacarta](#).

## Field arguments

In addition to the regular *form field arguments*, GeoDjango form fields take the following optional arguments.

### `srid`

#### `Field.srid`

This is the SRID code that the field value should be transformed to. For example, if the map widget SRID is different from the SRID more generally used by your application or database, the field will automatically convert input values into that SRID.

### `geom_type`

#### `Field.geom_type`

You generally shouldn't have to set or change that attribute which should be setup depending on the field class. It matches the OpenGIS standard geometry name.

## Form field classes

### `GeometryField`

```
class GeometryField
```

### `PointField`

```
class PointField
```

### `LineStringField`

```
class LineStringField
```

### `PolygonField`

```
class PolygonField
```

### `MultiPointField`

```
class MultiPointField
```

### `MultiLineStringField`

```
class MultiLineStringField
```

## MultiPolygonField

```
class MultiPolygonField
```

## GeometryCollectionField

```
class GeometryCollectionField
```

## Form widgets

GeoDjango form widgets allow you to display and edit geographic data on a visual map. Note that none of the currently available widgets supports 3D geometries, hence geometry fields will fallback using a simple `Textarea` widget for such data.

## Widget attributes

GeoDjango widgets are template-based, so their attributes are mostly different from other Django widget attributes.

`BaseGeometryWidget`. **`geom_type`**

The OpenGIS geometry type, generally set by the form field.

`BaseGeometryWidget`. **`map_height`**

`BaseGeometryWidget`. **`map_width`**

Height and width of the widget map (default is 400x600).

`BaseGeometryWidget`. **`map_srid`**

SRID code used by the map (default is 4326).

`BaseGeometryWidget`. **`display_raw`**

Boolean value specifying if a textarea input showing the serialized representation of the current geometry is visible, mainly for debugging purposes (default is `False`).

`BaseGeometryWidget`. **`supports_3d`**

Indicates if the widget supports edition of 3D data (default is `False`).

`BaseGeometryWidget`. **`template_name`**

The template used to render the map widget.

You can pass widget attributes in the same manner that for any other Django widget. For example:

```
from django.contrib.gis import forms

class MyGeoForm(forms.Form):
    point = forms.PointField(widget=
        forms.OSMWidget(attrs={'map_width': 800, 'map_height': 500}))
```

## Widget classes

`BaseGeometryWidget`

```
class BaseGeometryWidget
```

This is an abstract base widget containing the logic needed by subclasses. You cannot directly use this widget

for a geometry field. Note that the rendering of GeoDjango widgets is based on a template, identified by the `template_name` class attribute.

OpenLayersWidget

#### class `OpenLayersWidget`

This is the default widget used by all GeoDjango form fields. `template_name` is `gis/openlayers.html`.

`OpenLayersWidget` and `OSMWidget` use the `openlayers.js` file hosted on the `openlayers.org` website. This works for basic usage during development, but isn't appropriate for a production deployment as `openlayers.org/api/` has no guaranteed uptime and runs on a slow server. You are therefore advised to subclass these widgets in order to specify your own version of the `openlayers.js` file in the `js` property of the inner `Media` class (see *Assets as a static definition*). You can host a copy of `openlayers.js` tailored to your needs on your own server or refer to a copy from a content-delivery network like <https://cdnjs.com/>. This will also allow you to serve the JavaScript file(s) using the `https` protocol if needed.

OSMWidget

#### class `OSMWidget`

This widget uses an OpenStreetMap base layer (Mapnik) to display geographic objects on. `template_name` is `gis/openlayers-osm.html`.

The *OpenLayersWidget* note about JavaScript file hosting above also applies here. See also this [FAQ answer](#) about `https` access to map tiles.

## GeoQuerySet API Reference

class `GeoQuerySet` (*model=None*)

### Spatial Lookups

The spatial lookups in this section are available for `GeometryField` and `RasterField`.

For an introduction, see the *spatial lookups introduction*. For an overview of what lookups are compatible with a particular spatial backend, refer to the *spatial lookup compatibility table*.

Spatial lookups now support raster input.

### Lookups with rasters

All examples in the reference below are given for geometry fields and inputs, but the lookups can be used the same way with rasters on both sides. Whenever a lookup doesn't support raster input, the input is automatically converted to a geometry where necessary using the `ST_Polygon` function. See also the *introduction to raster lookups*.

The database operators used by the lookups can be divided into three categories:

- Native raster support N: the operator accepts rasters natively on both sides of the lookup, and raster input can be mixed with geometry inputs.
- Bilateral raster support B: the operator supports rasters only if both sides of the lookup receive raster inputs. Raster data is automatically converted to geometries for mixed lookups.
- Geometry conversion support C. The lookup does not have native raster support, all raster data is automatically converted to geometries.

The examples below show the SQL equivalent for the lookups in the different types of raster support. The same pattern applies to all spatial lookups.

Case	Lookup	SQL Equivalent
N, B	<code>rast__contains=rst</code>	<code>ST_Contains(rast, rst)</code>
N, B	<code>rast__1__contains=(rst, 2)</code>	<code>ST_Contains(rast, 1, rst, 2)</code>
B, C	<code>rast__contains=geom</code>	<code>ST_Contains(ST_Polygon(rast), geom)</code>
B, C	<code>rast__1__contains=geom</code>	<code>ST_Contains(ST_Polygon(rast, 1), geom)</code>
B, C	<code>poly__contains=rst</code>	<code>ST_Contains(poly, ST_Polygon(rst))</code>
B, C	<code>poly__contains=(rst, 1)</code>	<code>ST_Contains(poly, ST_Polygon(rst, 1))</code>
C	<code>rast__crosses=rst</code>	<code>ST_Crosses(ST_Polygon(rast), ST_Polygon(rst))</code>
C	<code>rast__1__crosses=(rst, 2)</code>	<code>ST_Crosses(ST_Polygon(rast, 1), ST_Polygon(rst, 2))</code>
C	<code>rast__crosses=geom</code>	<code>ST_Crosses(ST_Polygon(rast), geom)</code>
C	<code>poly__crosses=rst</code>	<code>ST_Crosses(poly, ST_Polygon(rst))</code>

Spatial lookups with rasters are only supported for PostGIS backends (denominated as PGRaster in this section).

### bbcontains

*Availability:* PostGIS, MySQL, SpatiaLite, PGRaster (Native)

Tests if the geometry or raster field's bounding box completely contains the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__bbcontains=geom)
```

Backend	SQL Equivalent
PostGIS	<code>poly ~ geom</code>
MySQL	<code>MBRContains(poly, geom)</code>
SpatiaLite	<code>MbrContains(poly, geom)</code>

### bboverlaps

*Availability:* PostGIS, MySQL, SpatiaLite, PGRaster (Native)

Tests if the geometry field's bounding box overlaps the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__bboverlaps=geom)
```

Backend	SQL Equivalent
PostGIS	<code>poly &amp;&amp; geom</code>
MySQL	<code>MBROverlaps(poly, geom)</code>
SpatiaLite	<code>MbrOverlaps(poly, geom)</code>

### contained

*Availability:* PostGIS, MySQL, SpatiaLite, PGRaster (Native)

Tests if the geometry field's bounding box is completely contained by the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__contained=geom)
```

Backend	SQL Equivalent
PostGIS	<code>poly @ geom</code>
MySQL	<code>MBRWithin(poly, geom)</code>
Spatialite	<code>MbrWithin(poly, geom)</code>

### **contains**

*Availability:* PostGIS, Oracle, MySQL, Spatialite, PGRaster (Bilateral)

Tests if the geometry field spatially contains the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__contains=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_Contains(poly, geom)</code>
Oracle	<code>SDO_CONTAINS(poly, geom)</code>
MySQL	<code>MBRContains(poly, geom)</code>
Spatialite	<code>Contains(poly, geom)</code>

### **contains\_properly**

*Availability:* PostGIS, PGRaster (Bilateral)

Returns true if the lookup geometry intersects the interior of the geometry field, but not the boundary (or exterior).<sup>4</sup>

Example:

```
Zipcode.objects.filter(poly__contains_properly=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_ContainsProperly(poly, geom)</code>

### **coveredby**

*Availability:* PostGIS, Oracle, PGRaster (Bilateral)

Tests if no point in the geometry field is outside the lookup geometry.<sup>3</sup>

Example:

```
Zipcode.objects.filter(poly__coveredby=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_CoveredBy(poly, geom)</code>
Oracle	<code>SDO_COVEREDBY(poly, geom)</code>

<sup>4</sup> Refer to the PostGIS [ST\\_ContainsProperly documentation](#) for more details.

<sup>3</sup> For an explanation of this routine, read [Quirks of the "Contains" Spatial Predicate](#) by Martin Davis (a PostGIS developer).

### covers

*Availability:* PostGIS, Oracle, PGRaster (Bilateral)

Tests if no point in the lookup geometry is outside the geometry field.<sup>3</sup>

Example:

```
Zipcode.objects.filter(poly__covers=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_Covers(poly, geom)</code>
Oracle	<code>SDO_COVERS(poly, geom)</code>

### crosses

*Availability:* PostGIS, SpatiaLite, PGRaster (Conversion)

Tests if the geometry field spatially crosses the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__crosses=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_Crosses(poly, geom)</code>
SpatiaLite	<code>Crosses(poly, geom)</code>

### disjoint

*Availability:* PostGIS, Oracle, MySQL, SpatiaLite, PGRaster (Bilateral)

Tests if the geometry field is spatially disjoint from the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__disjoint=geom)
```

Backend	SQL Equivalent
PostGIS	<code>ST_Disjoint(poly, geom)</code>
Oracle	<code>SDO_GEOM.RELATE(poly, 'DISJOINT', geom, 0.05)</code>
MySQL	<code>MBRDisjoint(poly, geom)</code>
SpatiaLite	<code>Disjoint(poly, geom)</code>

### equals

*Availability:* PostGIS, Oracle, MySQL, SpatiaLite, PGRaster (Conversion)

### exact, same\_as

*Availability:* PostGIS, Oracle, MySQL, SpatiaLite, PGRaster (Bilateral)

## intersects

*Availability:* PostGIS, Oracle, MySQL, SpatialLite, PGRaster (Bilateral)

Tests if the geometry field spatially intersects the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__intersects=geom)
```

Backend	SQL Equivalent
PostGIS	ST_Intersects(poly, geom)
Oracle	SDO_OVERLAPBDYINTERSECT(poly, geom)
MySQL	MBRIntersects(poly, geom)
SpatialLite	Intersects(poly, geom)

## isvalid

*Availability:* PostGIS

Tests if the geometry is valid.

Example:

```
Zipcode.objects.filter(poly__isvalid=True)
```

PostGIS equivalent:

```
SELECT ... WHERE ST_IsValid(poly)
```

## overlaps

*Availability:* PostGIS, Oracle, MySQL, SpatialLite, PGRaster (Bilateral)

## relate

*Availability:* PostGIS, Oracle, SpatialLite, PGRaster (Conversion)

Tests if the geometry field is spatially related to the lookup geometry by the values given in the given pattern. This lookup requires a tuple parameter, (geom, pattern); the form of pattern will depend on the spatial backend:

## PostGIS & SpatialLite

On these spatial backends the intersection pattern is a string comprising nine characters, which define intersections between the interior, boundary, and exterior of the geometry field and the lookup geometry. The intersection pattern matrix may only use the following characters: 1, 2, T, F, or \*. This lookup type allows users to “fine tune” a specific geometric relationship consistent with the DE-9IM model.<sup>1</sup>

Geometry example:

<sup>1</sup> See [OpenGIS Simple Feature Specification For SQL](#), at Ch. 2.1.13.2, p. 2-13 (The Dimensionally Extended Nine-Intersection Model).

```
# A tuple lookup parameter is used to specify the geometry and
# the intersection pattern (the pattern here is for 'contains').
Zipcode.objects.filter(poly__relate=(geom, 'T*T***FF*'))
```

PostGIS SQL equivalent:

```
SELECT ... WHERE ST_Relate(poly, geom, 'T*T***FF*')
```

Spatialite SQL equivalent:

```
SELECT ... WHERE Relate(poly, geom, 'T*T***FF*')
```

Raster example:

```
Zipcode.objects.filter(poly__relate=(rast, 1, 'T*T***FF*'))
Zipcode.objects.filter(rast__2__relate=(rast, 1, 'T*T***FF*'))
```

PostGIS SQL equivalent:

```
SELECT ... WHERE ST_Relate(poly, ST_Polygon(rast, 1), 'T*T***FF*')
SELECT ... WHERE ST_Relate(ST_Polygon(rast, 2), ST_Polygon(rast, 1), 'T*T***FF*')
```

## Oracle

Here the relation pattern is comprised of at least one of the nine relation strings: TOUCH, OVERLAPBDYDISJOINT, OVERLAPBDYINTERSECT, EQUAL, INSIDE, COVEREDBY, CONTAINS, COVERS, ON, and ANYINTERACT. Multiple strings may be combined with the logical Boolean operator OR, for example, 'inside+touch'.<sup>2</sup> The relation strings are case-insensitive.

Example:

```
Zipcode.objects.filter(poly__relate=(geom, 'anyinteract'))
```

Oracle SQL equivalent:

```
SELECT ... WHERE SDO_RELATE(poly, geom, 'anyinteract')
```

## touches

*Availability:* PostGIS, Oracle, MySQL, Spatialite

Tests if the geometry field spatially touches the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__touches=geom)
```

Backend	SQL Equivalent
PostGIS	ST_Touches(poly, geom)
MySQL	MBRTouches(poly, geom)
Oracle	SDO_TOUCH(poly, geom)
Spatialite	Touches(poly, geom)

<sup>2</sup> See `SDO_RELATE` documentation, from Ch. 11 of the Oracle Spatial User's Guide and Manual.

**within**

*Availability:* PostGIS, Oracle, MySQL, SpatialLite, PGRaster (Bilateral)

Tests if the geometry field is spatially within the lookup geometry.

Example:

```
Zipcode.objects.filter(poly__within=geom)
```

Backend	SQL Equivalent
PostGIS	ST_Within(poly, geom)
MySQL	MBRWithin(poly, geom)
Oracle	SDO_INSIDE(poly, geom)
SpatialLite	Within(poly, geom)

**left**

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box is strictly to the left of the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__left=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly << geom
```

**right**

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box is strictly to the right of the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__right=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly >> geom
```

**overlaps\_left**

*Availability:* PostGIS, PGRaster (Bilateral)

Tests if the geometry field's bounding box overlaps or is to the left of the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__overlaps_left=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly &< geom
```

### **overlaps\_right**

*Availability:* PostGIS, PGRaster (Bilateral)

Tests if the geometry field's bounding box overlaps or is to the right of the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__overlaps_right=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly &> geom
```

### **overlaps\_above**

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box overlaps or is above the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__overlaps_above=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly |&> geom
```

### **overlaps\_below**

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box overlaps or is below the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__overlaps_below=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly &<| geom
```

### **strictly\_above**

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box is strictly above the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__strictly_above=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly |>> geom
```

### `strictly_below`

*Availability:* PostGIS, PGRaster (Conversion)

Tests if the geometry field's bounding box is strictly below the lookup geometry's bounding box.

Example:

```
Zipcode.objects.filter(poly__strictly_below=geom)
```

PostGIS equivalent:

```
SELECT ... WHERE poly <<| geom
```

## Distance Lookups

*Availability:* PostGIS, Oracle, SpatiaLite, PGRaster (Native)

For an overview on performing distance queries, please refer to the *distance queries introduction*.

Distance lookups take the following form:

```
<field>__<distance lookup>=(<geometry/raster>, <distance value>[, 'spheroid'])
<field>__<distance lookup>=(<raster>, <band_index>, <distance value>[, 'spheroid'])
<field>__<band_index>__<distance lookup>=(<raster>, <band_index>, <distance value>[,
↪ 'spheroid'])
```

The value passed into a distance lookup is a tuple; the first two values are mandatory, and are the geometry to calculate distances to, and a distance value (either a number in units of the field, a *Distance* object, or a *query expression* [<ref/models/expressions>](#)). To pass a band index to the lookup, use a 3-tuple where the second entry is the band index.

With PostGIS, on every distance lookup but *dwithin*, an optional element, 'spheroid', may be included to tell GeoDjango to use the more accurate spheroid distance calculation functions on fields with a geodetic coordinate system (e.g., `ST_Distance_Spheroid` would be used instead of `ST_Distance_Sphere`). The simpler `ST_Distance` function is used with projected coordinate systems. Rasters are converted to geometries for spheroid based lookups.

The ability to pass an expression as the distance value was added.

### `distance_gt`

Returns models where the distance to the geometry field from the lookup geometry is greater than the given distance value.

Example:

```
Zipcode.objects.filter(poly__distance_gt=(geom, D(m=5)))
```

Backend	SQL Equivalent
PostGIS	<code>ST_Distance/ST_Distance_Sphere(poly, geom) &gt; 5</code>
Oracle	<code>SDO_GEOM.SDO_DISTANCE(poly, geom, 0.05) &gt; 5</code>
Spatialite	<code>Distance(poly, geom) &gt; 5</code>

### `distance_gte`

Returns models where the distance to the geometry field from the lookup geometry is greater than or equal to the given distance value.

Example:

```
Zipcode.objects.filter(poly__distance_gte=(geom, D(m=5)))
```

Backend	SQL Equivalent
PostGIS	<code>ST_Distance/ST_Distance_Sphere(poly, geom) &gt;= 5</code>
Oracle	<code>SDO_GEOM.SDO_DISTANCE(poly, geom, 0.05) &gt;= 5</code>
Spatialite	<code>Distance(poly, geom) &gt;= 5</code>

### `distance_lt`

Returns models where the distance to the geometry field from the lookup geometry is less than the given distance value.

Example:

```
Zipcode.objects.filter(poly__distance_lt=(geom, D(m=5)))
```

Backend	SQL Equivalent
PostGIS	<code>ST_Distance/ST_Distance_Sphere(poly, geom) &lt; 5</code>
Oracle	<code>SDO_GEOM.SDO_DISTANCE(poly, geom, 0.05) &lt; 5</code>
Spatialite	<code>Distance(poly, geom) &lt; 5</code>

### `distance_lte`

Returns models where the distance to the geometry field from the lookup geometry is less than or equal to the given distance value.

Example:

```
Zipcode.objects.filter(poly__distance_lte=(geom, D(m=5)))
```

Backend	SQL Equivalent
PostGIS	<code>ST_Distance/ST_Distance_Sphere(poly, geom) &lt;= 5</code>
Oracle	<code>SDO_GEOM.SDO_DISTANCE(poly, geom, 0.05) &lt;= 5</code>
Spatialite	<code>Distance(poly, geom) &lt;= 5</code>

### `dwithin`

Returns models where the distance to the geometry field from the lookup geometry are within the given distance from one another. Note that you can only provide `Distance` objects if the targeted geometries are in a projected system. For geographic geometries, you should use units of the geometry field (e.g. degrees for WGS84).

Example:

```
Zipcode.objects.filter(poly__dwithin=(geom, D(m=5)))
```

Backend	SQL Equivalent
PostGIS	<code>ST_DWithin(poly, geom, 5)</code>
Oracle	<code>SDO_WITHIN_DISTANCE(poly, geom, 5)</code>

**Note:** This lookup is not available on SpatiaLite.

## GeoQuerySet Methods

Deprecated since version 1.9: Using `GeoQuerySet` methods is now deprecated in favor of the new *Geographic Database Functions*. Albeit a little more verbose, they are much more powerful in how it is possible to combine them to build more complex queries.

`GeoQuerySet` methods specify that a spatial operation be performed on each spatial operation on each geographic field in the queryset and store its output in a new attribute on the model (which is generally the name of the `GeoQuerySet` method).

There are also aggregate `GeoQuerySet` methods which return a single value instead of a queryset. This section will describe the API and availability of every `GeoQuerySet` method available in GeoDjango.

**Note:** What methods are available depend on your spatial backend. See the *compatibility table* for more details.

With a few exceptions, the following keyword arguments may be used with all `GeoQuerySet` methods:

Keyword Argument	Description
<code>field_name</code>	By default, <code>GeoQuerySet</code> methods use the first geographic field encountered in the model. This keyword should be used to specify another geographic field (e.g., <code>field_name='point2'</code> ) when there are multiple geographic fields in a model. On PostGIS, the <code>field_name</code> keyword may also be used on geometry fields in models that are related via a <code>ForeignKey</code> relation (e.g., <code>field_name='related_point'</code> ).
<code>model_att</code>	By default, <code>GeoQuerySet</code> methods typically attach their output in an attribute with the same name as the <code>GeoQuerySet</code> method. Setting this keyword with the desired attribute name will override this default behavior. For example, <code>qs = Zipcode.objects.centroid(model_att='c')</code> will attach the centroid of the <code>Zipcode</code> geometry field in a <code>c</code> attribute on every model rather than in a <code>centroid</code> attribute. This keyword is required if a method name clashes with an existing <code>GeoQuerySet</code> method – if you wanted to use the <code>area()</code> method on model with a <code>PolygonField</code> named <code>area</code> , for example.

## Measurement

*Availability:* PostGIS, Oracle, SpatiaLite

### area

`GeoQuerySet.area(**kwargs)`

Deprecated since version 1.9: Use the [Area](#) function instead.

Returns the area of the geographic field in an `area` attribute on each element of this `GeoQuerySet`.

### distance

`GeoQuerySet.distance(geom, **kwargs)`

Deprecated since version 1.9: Use the [Distance](#) function instead.

This method takes a geometry as a parameter, and attaches a `distance` attribute to every model in the returned queryset that contains the distance (as a [Distance](#) object) to the given geometry.

In the following example (taken from the [GeoDjango distance tests](#)), the distance from the Tasmanian city of Hobart to every other [PointField](#) in the `AustraliaCity` queryset is calculated:

```
>>> pnt = AustraliaCity.objects.get(name='Hobart').point
>>> for city in AustraliaCity.objects.distance(pnt): print(city.name, city.distance)
Wollongong 990071.220408 m
Shellharbour 972804.613941 m
Thirroul 1002334.36351 m
Mittagong 975691.632637 m
Batemans Bay 834342.185561 m
Canberra 598140.268959 m
Melbourne 575337.765042 m
Sydney 1056978.87363 m
Hobart 0.0 m
Adelaide 1162031.83522 m
Hillsdale 1049200.46122 m
```

---

**Note:** Because the `distance` attribute is a [Distance](#) object, you can easily express the value in the units of your choice. For example, `city.distance.mi` is the distance value in miles and `city.distance.km` is the distance value in kilometers. See [Measurement Objects](#) for usage details and the list of [Supported units](#).

---

### length

`GeoQuerySet.length(**kwargs)`

Deprecated since version 1.9: Use the [Length](#) function instead.

Returns the length of the geometry field in a `length` attribute (a [Distance](#) object) on each model in the queryset.

## `perimeter`

`GeoQuerySet.perimeter(**kwargs)`

Deprecated since version 1.9: Use the `Perimeter` function instead.

Returns the perimeter of the geometry field in a `perimeter` attribute (a `Distance` object) on each model in the queryset.

## Geometry Relationships

The following methods take no arguments, and attach geometry objects each element of the `GeoQuerySet` that is the result of relationship function evaluated on the geometry field.

### `centroid`

`GeoQuerySet.centroid(**kwargs)`

Deprecated since version 1.9: Use the `Centroid` function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

Returns the centroid value for the geographic field in a `centroid` attribute on each element of the `GeoQuerySet`.

### `envelope`

`GeoQuerySet.envelope(**kwargs)`

Deprecated since version 1.9: Use the `Envelope` function instead.

*Availability:* PostGIS, SpatiaLite

Returns a geometry representing the bounding box of the geometry field in an `envelope` attribute on each element of the `GeoQuerySet`.

### `point_on_surface`

`GeoQuerySet.point_on_surface(**kwargs)`

Deprecated since version 1.9: Use the `PointOnSurface` function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

Returns a Point geometry guaranteed to lie on the surface of the geometry field in a `point_on_surface` attribute on each element of the queryset; otherwise sets with `None`.

## Geometry Editors

### `force_rhr`

`GeoQuerySet.force_rhr(**kwargs)`

Deprecated since version 1.9: Use the *ForceRHR* function instead.

*Availability:* PostGIS

Returns a modified version of the polygon/multipolygon in which all of the vertices follow the Right-Hand-Rule, and attaches as a `force_rhr` attribute on each element of the queryset.

### **reverse\_geom**

`GeoQuerySet.reverse_geom(**kwargs)`

Deprecated since version 1.9: Use the *Reverse* function instead.

*Availability:* PostGIS, Oracle

Reverse the coordinate order of the geometry field, and attaches as a `reverse` attribute on each element of the queryset.

### **scale**

`GeoQuerySet.scale(x, y, z=0.0, **kwargs)`

Deprecated since version 1.9: Use the *Scale* function instead.

*Availability:* PostGIS, SpatiaLite

### **snap\_to\_grid**

`GeoQuerySet.snap_to_grid(*args, **kwargs)`

Deprecated since version 1.9: Use the *SnapToGrid* function instead.

Snap all points of the input geometry to the grid. How the geometry is snapped to the grid depends on how many numeric (either float, integer, or long) arguments are given.

Number of Arguments	Description
1	A single size to snap bot the X and Y grids to.
2	X and Y sizes to snap the grid to.
4	X, Y sizes and the corresponding X, Y origins.

### **transform**

`GeoQuerySet.transform(srid=4326, **kwargs)`

Deprecated since version 1.9: Use the *Transform* function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

The `transform` method transforms the geometry field of a model to the spatial reference system specified by the `srid` parameter. If no `srid` is given, then 4326 (WGS84) is used by default.

---

**Note:** Unlike other `GeoQuerySet` methods, `transform` stores its output “in-place”. In other words, no new attribute for the transformed geometry is placed on the models.

---

---

**Note:** What spatial reference system an integer SRID corresponds to may depend on the spatial database used. In other words, the SRID numbers used for Oracle are not necessarily the same as those used by PostGIS.

---

Example:

```
>>> qs = Zipcode.objects.all().transform() # Transforms to WGS84
>>> qs = Zipcode.objects.all().transform(32140) # Transforming to "NAD83 / Texas_
↳South Central"
>>> print(qs[0].poly.srid)
32140
>>> print(qs[0].poly)
POLYGON ((234055.1698884720099159 4937796.9232223574072123 ...
```

### **translate**

`GeoQuerySet.translate(x, y, z=0.0, **kwargs)`

Deprecated since version 1.9: Use the *Translate* function instead.

Availability: PostGIS, SpatiaLite

Translates the geometry field to a new location using the given numeric parameters as offsets.

## **Geometry Operations**

Availability: PostGIS, Oracle, SpatiaLite

The following methods all take a geometry as a parameter and attach a geometry to each element of the `GeoQuerySet` that is the result of the operation.

### **difference**

`GeoQuerySet.difference(geom)`

Deprecated since version 1.9: Use the *Difference* function instead.

Returns the spatial difference of the geographic field with the given geometry in a *difference* attribute on each element of the `GeoQuerySet`.

### **intersection**

`GeoQuerySet.intersection(geom)`

Deprecated since version 1.9: Use the *Intersection* function instead.

Returns the spatial intersection of the geographic field with the given geometry in an *intersection* attribute on each element of the `GeoQuerySet`.

### **sym\_difference**

`GeoQuerySet.sym_difference(geom)`

Deprecated since version 1.9: Use the *SymDifference* function instead.

Returns the symmetric difference of the geographic field with the given geometry in a `sym_difference` attribute on each element of the `GeoQuerySet`.

### **union**

`GeoQuerySet.union(geom)`

Deprecated since version 1.9: Use the *Union* function instead.

Returns the union of the geographic field with the given geometry in an `union` attribute on each element of the `GeoQuerySet`.

## **Geometry Output**

The following `GeoQuerySet` methods will return an attribute that has the value of the geometry field in each model converted to the requested output format.

### **geohash**

`GeoQuerySet.geohash(precision=20, **kwargs)`

Deprecated since version 1.9: Use the *GeoHash* function instead.

Attaches a `geohash` attribute to every model the queryset containing the `GeoHash` representation of the geometry.

### **geojson**

`GeoQuerySet.geojson(**kwargs)`

Deprecated since version 1.9: Use the *AsGeoJSON* function instead.

*Availability:* PostGIS, SpatiaLite

Attaches a `geojson` attribute to every model in the queryset that contains the `GeoJSON` representation of the geometry.

Keyword Argument	Description
<code>precision</code>	It may be used to specify the number of significant digits for the coordinates in the GeoJSON representation – the default value is 8.
<code>crs</code>	Set this to <code>True</code> if you want the coordinate reference system to be included in the returned GeoJSON.
<code>bbox</code>	Set this to <code>True</code> if you want the bounding box to be included in the returned GeoJSON.

### **gml**

`GeoQuerySet.gml(**kwargs)`

Deprecated since version 1.9: Use the *AsGML* function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

Attaches a `gml` attribute to every model in the queryset that contains the [Geographic Markup Language \(GML\)](#) representation of the geometry.

Example:

```
>>> qs = Zipcode.objects.all().gml()
>>> print(qs[0].gml)
<gml:Polygon srsName="EPSG:4326"><gml:OuterBoundaryIs>-147.78711,70.245363 ... -147.
↪78711,70.245363</gml:OuterBoundaryIs></gml:Polygon>
```

Keyword Argument	Description
<code>precision</code>	This keyword is for PostGIS only. It may be used to specify the number of significant digits for the coordinates in the GML representation – the default value is 8.
<code>version</code>	This keyword is for PostGIS only. It may be used to specify the GML version used, and may only be values of 2 or 3. The default value is 2.

## **kml**

`GeoQuerySet.gml(**kwargs)`

Deprecated since version 1.9: Use the `AsKML` function instead.

*Availability:* PostGIS, SpatiaLite

Attaches a `kml` attribute to every model in the queryset that contains the [Keyhole Markup Language \(KML\)](#) representation of the geometry fields. It should be noted that the contents of the KML are transformed to WGS84 if necessary.

Example:

```
>>> qs = Zipcode.objects.all().kml()
>>> print(qs[0].kml)
<Polygon><outerBoundaryIs><LinearRing><coordinates>-103.04135,36.217596,0 ... -103.
↪04135,36.217596,0</coordinates></LinearRing></outerBoundaryIs></Polygon>
```

Keyword Argument	Description
<code>precision</code>	This keyword may be used to specify the number of significant digits for the coordinates in the KML representation – the default value is 8.

## **svg**

`GeoQuerySet.svg(**kwargs)`

Deprecated since version 1.9: Use the `AsSVG` function instead.

*Availability:* PostGIS, SpatiaLite

Attaches a `svg` attribute to every model in the queryset that contains the [Scalable Vector Graphics \(SVG\)](#) path data of the geometry fields.

Keyword Argument	Description
<code>relative</code>	If set to <code>True</code> , the path data will be implemented in terms of relative moves. Defaults to <code>False</code> , meaning that absolute moves are used instead.
<code>precision</code>	This keyword may be used to specify the number of significant digits for the coordinates in the SVG representation – the default value is 8.

## Miscellaneous

### `mem_size`

`GeoQuerySet.mem_size(**kwargs)`

Deprecated since version 1.9: Use the `MemSize` function instead.

*Availability:* PostGIS

Returns the memory size (number of bytes) that the geometry field takes in a `mem_size` attribute on each element of the `GeoQuerySet`.

### `num_geom`

`GeoQuerySet.num_geom(**kwargs)`

Deprecated since version 1.9: Use the `NumGeometries` function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

Returns the number of geometries in a `num_geom` attribute on each element of the `GeoQuerySet` if the geometry field is a collection (e.g., a `GEOMETRYCOLLECTION` or `MULTI*` field); otherwise sets with `None`.

### `num_points`

`GeoQuerySet.num_points(**kwargs)`

Deprecated since version 1.9: Use the `NumPoints` function instead.

*Availability:* PostGIS, Oracle, SpatiaLite

Returns the number of points in the first linestring in the geometry field in a `num_points` attribute on each element of the `GeoQuerySet`; otherwise sets with `None`.

## Aggregate Functions

Django provides some GIS-specific aggregate functions. For details on how to use these aggregate functions, see [the topic guide on aggregation](#).

Keyword Argument	Description
<code>tolerance</code>	This keyword is for Oracle only. It is for the tolerance value used by the <code>SDOAGGRTYPE</code> procedure; the <a href="#">Oracle documentation</a> has more details.

Example:

```
>>> from django.contrib.gis.db.models import Extent, Union
>>> WorldBorder.objects.aggregate(Extent('mpoly'), Union('mpoly'))
```

## Collect

```
class Collect (geo_field)
```

*Availability:* PostGIS, SpatiaLite

Returns a `GEOMETRYCOLLECTION` or a `MULTI` geometry object from the geometry column. This is analogous to a simplified version of the `Union` aggregate, except it can be several orders of magnitude faster than performing a union because it simply rolls up geometries into a collection or multi object, not caring about dissolving boundaries.

### Extent

**class Extent** (*geo\_field*)

*Availability:* PostGIS, Oracle, SpatiaLite

Returns the extent of all `geo_field` in the `QuerySet` as a four-tuple, comprising the lower left coordinate and the upper right coordinate.

Example:

```
>>> qs = City.objects.filter(name__in=('Houston', 'Dallas')).aggregate(Extent('poly'))
>>> print(qs['poly__extent'])
(-96.8016128540039, 29.7633724212646, -95.3631439208984, 32.782058715820)
```

### Extent3D

**class Extent3D** (*geo\_field*)

*Availability:* PostGIS

Returns the 3D extent of all `geo_field` in the `QuerySet` as a six-tuple, comprising the lower left coordinate and upper right coordinate (each with x, y, and z coordinates).

Example:

```
>>> qs = City.objects.filter(name__in=('Houston', 'Dallas')).aggregate(Extent3D('poly
↪'))
>>> print(qs['poly__extent3d'])
(-96.8016128540039, 29.7633724212646, 0, -95.3631439208984, 32.782058715820, 0)
```

### MakeLine

**class MakeLine** (*geo\_field*)

*Availability:* PostGIS, SpatiaLite

Returns a `LineString` constructed from the point field geometries in the `QuerySet`. Currently, ordering the queryset has no effect.

SpatiaLite support was added.

Example:

```
>>> qs = City.objects.filter(name__in=('Houston', 'Dallas')).aggregate(MakeLine('poly
↪'))
>>> print(qs['poly__makeline'])
LINESTRING (-95.363151000000020 29.7633739999999989, -96.8016109999999941 32.
↪7820570000000018)
```

## Union

**class** `Union` (*geo\_field*)

*Availability:* PostGIS, Oracle, Spatialite

This method returns a *GEOSGeometry* object comprising the union of every geometry in the queryset. Please note that use of `Union` is processor intensive and may take a significant amount of time on large querysets.

---

**Note:** If the computation time for using this method is too expensive, consider using *Collect* instead.

---

Example:

```
>>> u = Zipcode.objects.aggregate(Union(poly)) # This may take a long time.
>>> u = Zipcode.objects.filter(poly__within=bbbox).aggregate(Union(poly)) # A more_
↳sensible approach.
```

## Geographic Database Functions

The functions documented on this page allow users to access geographic database functions to be used in annotations, aggregations, or filters in Django.

Example:

```
>>> from django.contrib.gis.db.models.functions import Length
>>> Track.objects.annotate(length=Length('line')).filter(length__gt=100)
```

Not all backends support all functions, so refer to the documentation of each function to see if your database backend supports the function you want to use. If you call a geographic function on a backend that doesn't support it, you'll get a `NotImplementedError` exception.

Function's summary:

Measure-ment	Relationships	Operations	Editors	Output format	Miscellaneous
<i>Area</i>	<i>BoundingBox</i>	<i>Difference</i>	<i>ForceRHR</i>	<i>AsGeoJSON</i>	<i>IsValid</i>
<i>Distance</i>	<i>Centroid</i>	<i>Intersection</i>	<i>MakeValid</i>	<i>AsGML</i>	<i>MemSize</i>
<i>Length</i>	<i>Envelope</i>	<i>SymDifference</i>	<i>Reverse</i>	<i>AsKML</i>	<i>NumGeometries</i>
<i>Perimeter</i>	<i>PointOnSurface</i>	<i>Union</i>	<i>Scale</i>	<i>AsSVG</i>	<i>NumPoints</i>
			<i>SnapToGrid</i>	<i>GeoHash</i>	
			<i>Transform</i>		
			<i>Translate</i>		

## Area

**class** `Area` (*expression*, *\*\*extra*)

*Availability:* MySQL, Oracle, PostGIS, Spatialite

Accepts a single geographic field or expression and returns the area of the field as an *Area* measure. On MySQL, a raw float value is returned, as it's not possible to automatically determine the unit of the field.

**AsGeoJSON**

**class AsGeoJSON** (*expression*, *bbox=False*, *crs=False*, *precision=8*, *\*\*extra*)

*Availability:* PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns a [GeoJSON](#) representation of the geometry. Note that the result is not a complete GeoJSON structure but only the `geometry` key content of a GeoJSON structure. See also [GeoJSON Serializer](#).

Example:

```
>>> City.objects.annotate(json=AsGeoJSON('point')).get(name='Chicago').json
{"type": "Point", "coordinates": [-87.65018, 41.85039]}
```

Keyword Argument	Description
<code>bbox</code>	Set this to <code>True</code> if you want the bounding box to be included in the returned GeoJSON.
<code>crs</code>	Set this to <code>True</code> if you want the coordinate reference system to be included in the returned GeoJSON.
<code>precision</code>	It may be used to specify the number of significant digits for the coordinates in the GeoJSON representation – the default value is 8.

**AsGML**

**class AsGML** (*expression*, *version=2*, *precision=8*, *\*\*extra*)

*Availability:* PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns a [Geographic Markup Language \(GML\)](#) representation of the geometry.

Example:

```
>>> qs = Zipcode.objects.annotate(gml=AsGML('poly'))
>>> print(qs[0].gml)
<gml:Polygon srsName="EPSG:4326"><gml:OuterBoundaryIs>-147.78711,70.245363 ...
-147.78711,70.245363</gml:OuterBoundaryIs></gml:Polygon>
```

Keyword Argument	Description
<code>precision</code>	Specifies the number of significant digits for the coordinates in the GML representation – the default value is 8.
<code>version</code>	Specifies the GML version to use: 2 (default) or 3.

**AsKML**

**class AsKML** (*expression*, *precision=8*, *\*\*extra*)

*Availability:* PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns a [Keyhole Markup Language \(KML\)](#) representation of the geometry.

Example:

```
>>> qs = Zipcode.objects.annotate(kml=AsKML('poly'))
>>> print(qs[0].kml)
<Polygon><outerBoundaryIs><LinearRing><coordinates>-103.04135,36.217596,0 ...
-103.04135,36.217596,0</coordinates></LinearRing></outerBoundaryIs></Polygon>
```

Keyword Argument	Description
<code>precision</code>	This keyword may be used to specify the number of significant digits for the coordinates in the KML representation – the default value is 8.

### AsSVG

**class AsSVG** (*expression*, *relative=False*, *precision=8*, *\*\*extra*)

*Availability:* PostGIS, SpatialLite

Accepts a single geographic field or expression and returns a Scalable Vector Graphics (SVG) representation of the geometry.

Keyword Argument	Description
<code>relative</code>	If set to <code>True</code> , the path data will be implemented in terms of relative moves. Defaults to <code>False</code> , meaning that absolute moves are used instead.
<code>precision</code>	This keyword may be used to specify the number of significant digits for the coordinates in the SVG representation – the default value is 8.

### BoundingCircle

**class BoundingCircle** (*expression*, *num\_seg=48*, *\*\*extra*)

*Availability:* PostGIS

Accepts a single geographic field or expression and returns the smallest circle polygon that can fully contain the geometry.

### Centroid

**class Centroid** (*expression*, *\*\*extra*)

*Availability:* MySQL, PostGIS, Oracle, SpatialLite

Accepts a single geographic field or expression and returns the `centroid` value of the geometry.

### Difference

**class Difference** (*expr1*, *expr2*, *\*\*extra*)

*Availability:* MySQL ( $\geq 5.6.1$ ), PostGIS, Oracle, SpatialLite

Accepts two geographic fields or expressions and returns the geometric difference, that is the part of geometry A that does not intersect with geometry B.

MySQL support was added.

## Distance

**class Distance** (*expr1, expr2, spheroid=None, \*\*extra*)

*Availability:* MySQL ( $\geq 5.6.1$ ), PostGIS, Oracle, SpatiaLite

Accepts two geographic fields or expressions and returns the distance between them, as a *Distance* object. On MySQL, a raw float value is returned, as it's not possible to automatically determine the unit of the field.

On backends that support distance calculation on geodetic coordinates, the proper backend function is automatically chosen depending on the SRID value of the geometries (e.g. `ST_Distance_Sphere` on PostGIS).

When distances are calculated with geodetic (angular) coordinates, as is the case with the default WGS84 (4326) SRID, you can set the `spheroid` keyword argument to decide if the calculation should be based on a simple sphere (less accurate, less resource-intensive) or on a spheroid (more accurate, more resource-intensive).

In the following example, the distance from the city of Hobart to every other *PointField* in the `AustraliaCity` queryset is calculated:

```
>>> from django.contrib.gis.db.models.functions import Distance
>>> pnt = AustraliaCity.objects.get(name='Hobart').point
>>> for city in AustraliaCity.objects.annotate(distance=Distance('point', pnt)):
...     print(city.name, city.distance)
Wollongong 990071.220408 m
Shellharbour 972804.613941 m
Thirroul 1002334.36351 m
...
```

---

**Note:** Because the `distance` attribute is a *Distance* object, you can easily express the value in the units of your choice. For example, `city.distance.mi` is the distance value in miles and `city.distance.km` is the distance value in kilometers. See *Measurement Objects* for usage details and the list of *Supported units*.

---

## Envelope

**class Envelope** (*expression, \*\*extra*)

*Availability:* MySQL, PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns the geometry representing the bounding box of the geometry.

## ForceRHR

**class ForceRHR** (*expression, \*\*extra*)

*Availability:* PostGIS

Accepts a single geographic field or expression and returns a modified version of the polygon/multipolygon in which all of the vertices follow the right-hand rule.

## GeoHash

**class GeoHash** (*expression, precision=None, \*\*extra*)

*Availability:* PostGIS, SpatiaLite ( $\geq 4.0$ , LWGEOM)

Accepts a single geographic field or expression and returns a `GeoHash` representation of the geometry.

The `precision` keyword argument controls the number of characters in the result.

SpatiaLite support was added.

### Intersection

**class Intersection** (*expr1*, *expr2*, *\*\*extra*)

*Availability:* MySQL ( $\geq 5.6.1$ ), PostGIS, Oracle, SpatiaLite

Accepts two geographic fields or expressions and returns the geometric intersection between them.

MySQL support was added.

### IsValid

**class IsValid** (*expr*)

*Availability:* PostGIS

Accepts a geographic field or expression and tests if the value is well formed. Returns `True` if its value is a valid geometry and `False` otherwise.

### Length

**class Length** (*expression*, *spheroid=True*, *\*\*extra*)

*Availability:* MySQL, Oracle, PostGIS, SpatiaLite

Accepts a single geographic linestring or multilinestring field or expression and returns its length as an *Distance* measure. On MySQL, a raw float value is returned, as it's not possible to automatically determine the unit of the field.

On PostGIS and SpatiaLite, when the coordinates are geodetic (angular), you can specify if the calculation should be based on a simple sphere (less accurate, less resource-intensive) or on a spheroid (more accurate, more resource-intensive) with the `spheroid` keyword argument.

### MakeValid

**class MakeValid** (*expr*)

*Availability:* PostGIS

Accepts a geographic field or expression and attempts to convert the value into a valid geometry without losing any of the input vertices. Geometries that are already valid are returned without changes. Simple polygons might become a multipolygon and the result might be of lower dimension than the input.

### MemSize

**class MemSize** (*expression*, *\*\*extra*)

*Availability:* PostGIS

Accepts a single geographic field or expression and returns the memory size (number of bytes) that the geometry field takes.

### **NumGeometries**

**class NumGeometries** (*expression*, *\*\*extra*)

*Availability:* MySQL, PostGIS, Oracle, Spatialite

Accepts a single geographic field or expression and returns the number of geometries if the geometry field is a collection (e.g., a GEOMETRYCOLLECTION or MULTI\* field); otherwise returns `None`.

### **NumPoints**

**class NumPoints** (*expression*, *\*\*extra*)

*Availability:* MySQL, PostGIS, Oracle, Spatialite

Accepts a single geographic field or expression and returns the number of points in the first linestring in the geometry field; otherwise returns `None`.

### **Perimeter**

**class Perimeter** (*expression*, *\*\*extra*)

*Availability:* PostGIS, Oracle, Spatialite ( $\geq 4.0$ )

Accepts a single geographic field or expression and returns the perimeter of the geometry field as a *Distance* object.

### **PointOnSurface**

**class PointOnSurface** (*expression*, *\*\*extra*)

*Availability:* PostGIS, Oracle, Spatialite

Accepts a single geographic field or expression and returns a `Point` geometry guaranteed to lie on the surface of the field; otherwise returns `None`.

### **Reverse**

**class Reverse** (*expression*, *\*\*extra*)

*Availability:* PostGIS, Oracle, Spatialite ( $\geq 4.0$ )

Accepts a single geographic field or expression and returns a geometry with reversed coordinates.

### **Scale**

**class Scale** (*expression*, *x*, *y*, *z=0.0*, *\*\*extra*)

*Availability:* PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns a geometry with scaled coordinates by multiplying them with the *x*, *y*, and optionally *z* parameters.

### **SnapToGrid**

**class SnapToGrid** (*expression*, \**args*, \*\**extra*)

*Availability:* PostGIS, SpatiaLite (≥ 3.1)

Accepts a single geographic field or expression and returns a geometry with all points snapped to the given grid. How the geometry is snapped to the grid depends on how many numeric (either float, integer, or long) arguments are given.

Number of Arguments	Description
1	A single size to snap both the X and Y grids to.
2	X and Y sizes to snap the grid to.
4	X, Y sizes and the corresponding X, Y origins.

### **SymDifference**

**class SymDifference** (*expr1*, *expr2*, \*\**extra*)

*Availability:* MySQL (≥ 5.6.1), PostGIS, Oracle, SpatiaLite

Accepts two geographic fields or expressions and returns the geometric symmetric difference (union without the intersection) between the given parameters.

MySQL support was added.

### **Transform**

**class Transform** (*expression*, *srid*, \*\**extra*)

*Availability:* PostGIS, Oracle, SpatiaLite

Accepts a geographic field or expression and a SRID integer code, and returns the transformed geometry to the spatial reference system specified by the `srid` parameter.

---

**Note:** What spatial reference system an integer SRID corresponds to may depend on the spatial database used. In other words, the SRID numbers used for Oracle are not necessarily the same as those used by PostGIS.

---

### **Translate**

**class Translate** (*expression*, *x*, *y*, *z=0.0*, \*\**extra*)

*Availability:* PostGIS, SpatiaLite

Accepts a single geographic field or expression and returns a geometry with its coordinates offset by the *x*, *y*, and optionally *z* numeric parameters.

## Union

```
class Union (expr1, expr2, **extra)
```

Availability: MySQL ( $\geq 5.6.1$ ), PostGIS, Oracle, Spatialite

Accepts two geographic fields or expressions and returns the union of both geometries.

## Measurement Objects

The `django.contrib.gis.measure` module contains objects that allow for convenient representation of distance and area units of measure.<sup>1</sup> Specifically, it implements two objects, `Distance` and `Area` – both of which may be accessed via the `D` and `A` convenience aliases, respectively.

## Example

`Distance` objects may be instantiated using a keyword argument indicating the context of the units. In the example below, two different distance objects are instantiated in units of kilometers (km) and miles (mi):

```
>>> from django.contrib.gis.measure import Distance, D
>>> d1 = Distance(km=5)
>>> print(d1)
5.0 km
>>> d2 = D(mi=5) # `D` is an alias for `Distance`
>>> print(d2)
5.0 mi
```

Conversions are easy, just access the preferred unit attribute to get a converted distance quantity:

```
>>> print(d1.mi) # Converting 5 kilometers to miles
3.10685596119
>>> print(d2.km) # Converting 5 miles to kilometers
8.04672
```

Moreover, arithmetic operations may be performed between the distance objects:

```
>>> print(d1 + d2) # Adding 5 miles to 5 kilometers
13.04672 km
>>> print(d2 - d1) # Subtracting 5 kilometers from 5 miles
1.89314403881 mi
```

Two `Distance` objects multiplied together will yield an `Area` object, which uses squared units of measure:

```
>>> a = d1 * d2 # Returns an Area object.
>>> print(a)
40.2336 sq_km
```

To determine what the attribute abbreviation of a unit is, the `unit_attname` class method may be used:

```
>>> print(Distance.unit_attname('US Survey Foot'))
survey_ft
>>> print(Distance.unit_attname('centimeter'))
cm
```

<sup>1</sup> Robert Coup is the initial author of the measure objects, and was inspired by Brian Beck's work in `geopy` and Geoff Biggs' PhD work on dimensioned units for robotics.

## Supported units

Unit Attribute	Full name or alias(es)
km	Kilometre, Kilometer
mi	Mile
m	Meter, Metre
yd	Yard
ft	Foot, Foot (International)
survey_ft	U.S. Foot, US survey foot
inch	Inches
cm	Centimeter
mm	Millimetre, Millimeter
um	Micrometer, Micrometre
british_ft	British foot (Sears 1922)
british_yd	British yard (Sears 1922)
british_chain_sears	British chain (Sears 1922)
indian_yd	Indian yard, Yard (Indian)
sears_yd	Yard (Sears)
clarke_ft	Clarke's Foot
chain	Chain
chain_benoit	Chain (Benoit)
chain_sears	Chain (Sears)
british_chain_benoit	British chain (Benoit 1895 B)
british_chain_sears_truncated	British chain (Sears 1922 truncated)
gold_coast_ft	Gold Coast foot
link	Link
link_benoit	Link (Benoit)
link_sears	Link (Sears)
clarke_link	Clarke's link
fathom	Fathom
rod	Rod
nm	Nautical Mile
nm_uk	Nautical Mile (UK)
german_m	German legal metre

---

**Note:** *Area* attributes are the same as *Distance* attributes, except they are prefixed with `sq_` (area units are square in nature). For example, `Area(sq_m=2)` creates an *Area* object representing two square meters.

---

## Measurement API

### Distance

**class** `Distance` (*\*\*kwargs*)

To initialize a distance object, pass in a keyword corresponding to the desired *unit attribute name* set with desired value. For example, the following creates a distance object representing 5 miles:

```
>>> dist = Distance(mi=5)
```

`__getattr__ (unit_att)`

Returns the distance value in units corresponding to the given unit attribute. For example:

```
>>> print (dist.km)
8.04672
```

**classmethod** `unit_attname (unit_name)`

Returns the distance unit attribute name for the given full unit name. For example:

```
>>> Distance.unit_attname ('Mile')
'mi'
```

#### class **D**

Alias for *Distance* class.

#### Area

#### class **Area** (\*\*kwargs)

To initialize an area object, pass in a keyword corresponding to the desired *unit attribute name* set with desired value. For example, the following creates an area object representing 5 square miles:

```
>>> a = Area(sq_mi=5)
```

`__getattr__ (unit_att)`

Returns the area value in units corresponding to the given unit attribute. For example:

```
>>> print (a.sq_km)
12.949940551680001
```

**classmethod** `unit_attname (unit_name)`

Returns the area unit attribute name for the given full unit name. For example:

```
>>> Area.unit_attname ('Kilometer')
'sq_km'
```

#### class **A**

Alias for *Area* class.

## GEOS API

### Background

#### What is GEOS?

GEOS stands for **Geometry Engine - Open Source**, and is a C++ library, ported from the [Java Topology Suite](#). GEOS implements the [OpenGIS Simple Features for SQL](#) spatial predicate functions and spatial operators. GEOS, now an OSGeo project, was initially developed and maintained by [Refractions Research](#) of Victoria, Canada.

## Features

GeoDjango implements a high-level Python wrapper for the GEOS library, its features include:

- A BSD-licensed interface to the GEOS geometry routines, implemented purely in Python using `ctypes`.
- Loosely-coupled to GeoDjango. For example, `GEOSGeometry` objects may be used outside of a Django project/application. In other words, no need to have `DJANGO_SETTINGS_MODULE` set or use a database, etc.
- Mutability: `GEOSGeometry` objects may be modified.
- Cross-platform and tested; compatible with Windows, Linux, Solaris, and Mac OS X platforms.

## Tutorial

This section contains a brief introduction and tutorial to using `GEOSGeometry` objects.

### Creating a Geometry

`GEOSGeometry` objects may be created in a few ways. The first is to simply instantiate the object on some spatial input – the following are examples of creating the same geometry from WKT, HEX, WKB, and GeoJSON:

```
>>> from django.contrib.gis.geos import GEOSGeometry
>>> pnt = GEOSGeometry('POINT(5 23)') # WKT
>>> pnt = GEOSGeometry('01010000000000000000000000144000000000000003740') # HEX
>>> pnt = GEOSGeometry(buffer(
↳ '\x01\x01\x00\x00\x00\x00\x00\x00\x00\x00\x00\x00\x00\x14@\x00\x00\x00\x00\x00\x007@')
>>> pnt = GEOSGeometry({'type': "Point", "coordinates": [ 5.000000, 23.000000 ] })
↳ # GeoJSON
```

Another option is to use the constructor for the specific geometry type that you wish to create. For example, a `Point` object may be created by passing in the X and Y coordinates into its constructor:

```
>>> from django.contrib.gis.geos import Point
>>> pnt = Point(5, 23)
```

All these constructors take the keyword argument `srid`. For example:

```
>>> from django.contrib.gis.geos import GEOSGeometry, LineString, Point
>>> print(GEOSGeometry('POINT (0 0)', srid=4326))
SRID=4326;POINT (0 0)
>>> print(LineString((0, 0), (1, 1), srid=4326))
SRID=4326;LINESTRING (0 0, 1 1)
>>> print(Point(0, 0, srid=32140))
SRID=32140;POINT (0 0)
```

Finally, there is the `fromfile()` factory method which returns a `GEOSGeometry` object from a file:

```
>>> from django.contrib.gis.geos import fromfile
>>> pnt = fromfile('/path/to/pnt.wkt')
>>> pnt = fromfile(open('/path/to/pnt.wkt'))
```

---

### My logs are filled with GEOS-related errors

You find many `TypeError` or `AttributeError` exceptions filling your Web server's log files. This generally means that you are creating GEOS objects at the top level of some of your Python modules. Then, due to a race

condition in the garbage collector, your module is garbage collected before the GEOS object. To prevent this, create *GEOSGeometry* objects inside the local scope of your functions/methods.

## Geometries are Pythonic

*GEOSGeometry* objects are ‘Pythonic’, in other words components may be accessed, modified, and iterated over using standard Python conventions. For example, you can iterate over the coordinates in a *Point*:

```
>>> pnt = Point(5, 23)
>>> [coord for coord in pnt]
[5.0, 23.0]
```

With any geometry object, the *GEOSGeometry.coords* property may be used to get the geometry coordinates as a Python tuple:

```
>>> pnt.coords
(5.0, 23.0)
```

You can get/set geometry components using standard Python indexing techniques. However, what is returned depends on the geometry type of the object. For example, indexing on a *LineString* returns a coordinate tuple:

```
>>> from django.contrib.gis.geos import LineString
>>> line = LineString((0, 0), (0, 50), (50, 50), (50, 0), (0, 0))
>>> line[0]
(0.0, 0.0)
>>> line[-2]
(50.0, 0.0)
```

Whereas indexing on a *Polygon* will return the ring (a *LinearRing* object) corresponding to the index:

```
>>> from django.contrib.gis.geos import Polygon
>>> poly = Polygon(((0.0, 0.0), (0.0, 50.0), (50.0, 50.0), (50.0, 0.0), (0.0, 0.0)))
>>> poly[0]
<LinearRing object at 0x1044395b0>
>>> poly[0][-2] # second-to-last coordinate of external ring
(50.0, 0.0)
```

In addition, coordinates/components of the geometry may added or modified, just like a Python list:

```
>>> line[0] = (1.0, 1.0)
>>> line.pop()
(0.0, 0.0)
>>> line.append((1.0, 1.0))
>>> line.coords
((1.0, 1.0), (0.0, 50.0), (50.0, 50.0), (50.0, 0.0), (1.0, 1.0))
```

Geometries support set-like operators:

```
>>> from django.contrib.gis.geos import LineString
>>> ls1 = LineString((0, 0), (2, 2))
>>> ls2 = LineString((1, 1), (3, 3))
>>> print(ls1 | ls2) # equivalent to `ls1.union(ls2)`
MULTILINESTRING ((0 0, 1 1), (1 1, 2 2), (2 2, 3 3))
>>> print(ls1 & ls2) # equivalent to `ls1.intersection(ls2)`
LINESTRING (1 1, 2 2)
>>> print(ls1 - ls2) # equivalent to `ls1.difference(ls2)`
```

```
LINESTRING(0 0, 1 1)
>>> print(ls1 ^ ls2) # equivalent to `ls1.sym_difference(ls2)`
MULTILINESTRING ((0 0, 1 1), (2 2, 3 3))
```

---

### Equality operator doesn't check spatial equality

The `GEOSGeometry` equality operator uses `equals_exact()`, not `equals()`, i.e. it requires the compared geometries to have the same coordinates in the same positions:

```
>>> from django.contrib.gis.geos import LineString
>>> ls1 = LineString((0, 0), (1, 1))
>>> ls2 = LineString((1, 1), (0, 0))
>>> ls1.equals(ls2)
True
>>> ls1 == ls2
False
```

---

## Geometry Objects

### GEOSGeometry

`class GEOSGeometry (geo_input, srid=None)`

#### Parameters

- **geo\_input** – Geometry input value (string or buffer)
- **srid** (*int*) – spatial reference identifier

This is the base class for all GEOS geometry objects. It initializes on the given `geo_input` argument, and then assumes the proper geometry subclass (e.g., `GEOSGeometry('POINT(1 1)')` will create a `Point` object).

The following input formats, along with their corresponding Python types, are accepted:

Format	Input Type
WKT / EWKT	<code>str</code> or <code>unicode</code>
HEX / HEXEWKB	<code>str</code> or <code>unicode</code>
WKB / EWKB	<code>buffer</code>
GeoJSON (requires GDAL)	<code>str</code> or <code>unicode</code>

### Properties

#### `GEOSGeometry.coords`

Returns the coordinates of the geometry as a tuple.

#### `GEOSGeometry.dims`

Returns the dimension of the geometry:

- 0 for `Points` and `MultiPoints`
- 1 for `LineStrings` and `MultiLineStrings`
- 2 for `Polygons` and `MultiPolygons`
- -1 for empty `GeometryCollections`

- the maximum dimension of its elements for non-empty *GeometryCollections*

`GEOSGeometry.empty`

Returns whether or not the set of points in the geometry is empty.

`GEOSGeometry.geom_type`

Returns a string corresponding to the type of geometry. For example:

```
>>> pnt = GEOSGeometry('POINT(5 23)')
>>> pnt.geom_type
'Point'
```

`GEOSGeometry.geom_typeid`

Returns the GEOS geometry type identification number. The following table shows the value for each geometry type:

Geometry	ID
<i>Point</i>	0
<i>LineString</i>	1
<i>LinearRing</i>	2
<i>Polygon</i>	3
<i>MultiPoint</i>	4
<i>MultiLineString</i>	5
<i>MultiPolygon</i>	6
<i>GeometryCollection</i>	7

`GEOSGeometry.num_coords`

Returns the number of coordinates in the geometry.

`GEOSGeometry.num_geom`

Returns the number of geometries in this geometry. In other words, will return 1 on anything but geometry collections.

`GEOSGeometry.hasz`

Returns a boolean indicating whether the geometry is three-dimensional.

`GEOSGeometry.ring`

Returns a boolean indicating whether the geometry is a *LinearRing*.

`GEOSGeometry.simple`

Returns a boolean indicating whether the geometry is ‘simple’. A geometry is simple if and only if it does not intersect itself (except at boundary points). For example, a *LineString* object is not simple if it intersects itself. Thus, *LinearRing* and *Polygon* objects are always simple because they do cannot intersect themselves, by definition.

`GEOSGeometry.valid`

Returns a boolean indicating whether the geometry is valid.

`GEOSGeometry.valid_reason`

Returns a string describing the reason why a geometry is invalid.

`GEOSGeometry.srid`

Property that may be used to retrieve or set the SRID associated with the geometry. For example:

```
>>> pnt = Point(5, 23)
>>> print(pnt.srid)
None
>>> pnt.srid = 4326
>>> pnt.srid
4326
```

## Output Properties

The properties in this section export the *GEOSGeometry* object into a different. This output may be in the form of a string, buffer, or even another object.

### *GEOSGeometry*.ewkt

Returns the “extended” Well-Known Text of the geometry. This representation is specific to PostGIS and is a superset of the OGC WKT standard.<sup>1</sup> Essentially the SRID is prepended to the WKT representation, for example `SRID=4326;POINT(5 23)`.

---

**Note:** The output from this property does not include the 3dm, 3dz, and 4d information that PostGIS supports in its EWKT representations.

---

### *GEOSGeometry*.hex

Returns the WKB of this Geometry in hexadecimal form. Please note that the SRID value is not included in this representation because it is not a part of the OGC specification (use the *GEOSGeometry.hexewkb* property instead).

### *GEOSGeometry*.hexewkb

Returns the EWKB of this Geometry in hexadecimal form. This is an extension of the WKB specification that includes the SRID value that are a part of this geometry.

### *GEOSGeometry*.json

Returns the GeoJSON representation of the geometry. Note that the result is not a complete GeoJSON structure but only the `geometry` key content of a GeoJSON structure. See also *GeoJSON Serializer*.

### *GEOSGeometry*.geojson

Alias for *GEOSGeometry.json*.

### *GEOSGeometry*.kml

Returns a KML (Keyhole Markup Language) representation of the geometry. This should only be used for geometries with an SRID of 4326 (WGS84), but this restriction is not enforced.

### *GEOSGeometry*.ogr

Returns an *OGRGeometry* object corresponding to the GEOS geometry.

---

**Note:** Requires GDAL.

---

### *GEOSGeometry*.wkb

Returns the WKB (Well-Known Binary) representation of this Geometry as a Python buffer. SRID value is not included, use the *GEOSGeometry.ewkb* property instead.

### *GEOSGeometry*.ewkb

Return the EWKB representation of this Geometry as a Python buffer. This is an extension of the WKB specification that includes any SRID value that are a part of this geometry.

### *GEOSGeometry*.wkt

Returns the Well-Known Text of the geometry (an OGC standard).

Non-significant zeros are stripped from the output.

---

<sup>1</sup> See PostGIS EWKB, EWKT and Canonical Forms, PostGIS documentation at Ch. 4.1.2.

## Spatial Predicate Methods

All of the following spatial predicate methods take another *GEOSGeometry* instance (*other*) as a parameter, and return a boolean.

*GEOSGeometry*.**contains** (*other*)

Returns True if *other.within(this)* returns True.

*GEOSGeometry*.**covers** (*other*)

Returns True if this geometry covers the specified geometry.

The covers predicate has the following equivalent definitions:

- Every point of the other geometry is a point of this geometry.
- The DE-9IM Intersection Matrix for the two geometries is T\*\*\*\*\*FF\*, \*T\*\*\*\*\*FF\*, \*\*\*T\*FF\*, or \*\*\*\*T\*FF\*.

If either geometry is empty, returns False.

This predicate is similar to *GEOSGeometry.contains()*, but is more inclusive (i.e. returns True for more cases). In particular, unlike *contains()* it does not distinguish between points in the boundary and in the interior of geometries. For most situations, *covers()* should be preferred to *contains()*. As an added benefit, *covers()* is more amenable to optimization and hence should outperform *contains()*.

*GEOSGeometry*.**crosses** (*other*)

Returns True if the DE-9IM intersection matrix for the two Geometries is T\*T\*\*\*\*\* (for a point and a curve, a point and an area or a line and an area) 0\*\*\*\*\* (for two curves).

*GEOSGeometry*.**disjoint** (*other*)

Returns True if the DE-9IM intersection matrix for the two geometries is FF\*FF\*\*\*\*.

*GEOSGeometry*.**equals** (*other*)

Returns True if the DE-9IM intersection matrix for the two geometries is T\*F\*\*FFF\*.

*GEOSGeometry*.**equals\_exact** (*other*, *tolerance=0*)

Returns true if the two geometries are exactly equal, up to a specified tolerance. The tolerance value should be a floating point number representing the error tolerance in the comparison, e.g., `poly1.equals_exact(poly2, 0.001)` will compare equality to within one thousandth of a unit.

*GEOSGeometry*.**intersects** (*other*)

Returns True if *GEOSGeometry.disjoint()* is False.

*GEOSGeometry*.**overlaps** (*other*)

Returns true if the DE-9IM intersection matrix for the two geometries is T\*T\*\*\*T\*\* (for two points or two surfaces) 1\*T\*\*\*T\*\* (for two curves).

*GEOSGeometry*.**relate\_pattern** (*other*, *pattern*)

Returns True if the elements in the DE-9IM intersection matrix for this geometry and the other matches the given *pattern* – a string of nine characters from the alphabet: {T, F, \*, 0}.

*GEOSGeometry*.**touches** (*other*)

Returns True if the DE-9IM intersection matrix for the two geometries is FT\*\*\*\*\*, F\*\*T\*\*\*\*\* or F\*\*\*T\*\*\*\*.

*GEOSGeometry*.**within** (*other*)

Returns True if the DE-9IM intersection matrix for the two geometries is T\*F\*\*F\*\*\*\*.

## Topological Methods

`GEOSGeometry.buffer` (*width*, *quadsegs*=8)

Returns a *GEOSGeometry* that represents all points whose distance from this geometry is less than or equal to the given width. The optional *quadsegs* keyword sets the number of segments used to approximate a quarter circle (defaults is 8).

`GEOSGeometry.difference` (*other*)

Returns a *GEOSGeometry* representing the points making up this geometry that do not make up other.

`GEOSGeometry.interpolate` (*distance*)

`GEOSGeometry.interpolate_normalized` (*distance*)

Given a distance (float), returns the point (or closest point) within the geometry (*LineString* or *MultiLineString*) at that distance. The normalized version takes the distance as a float between 0 (origin) and 1 (endpoint).

Reverse of *GEOSGeometry.project* ().

`GEOSGeometry.intersection` (*other*)

Returns a *GEOSGeometry* representing the points shared by this geometry and other.

`GEOSGeometry.project` (*point*)

`GEOSGeometry.project_normalized` (*point*)

Returns the distance (float) from the origin of the geometry (*LineString* or *MultiLineString*) to the point projected on the geometry (that is to a point of the line the closest to the given point). The normalized version returns the distance as a float between 0 (origin) and 1 (endpoint).

Reverse of *GEOSGeometry.interpolate* ().

`GEOSGeometry.relate` (*other*)

Returns the DE-9IM intersection matrix (a string) representing the topological relationship between this geometry and the other.

`GEOSGeometry.simplify` (*tolerance*=0.0, *preserve\_topology*=False)

Returns a new *GEOSGeometry*, simplified to the specified tolerance using the Douglas-Peucker algorithm. A higher tolerance value implies fewer points in the output. If no tolerance is provided, it defaults to 0.

By default, this function does not preserve topology. For example, *Polygon* objects can be split, be collapsed into lines, or disappear. *Polygon* holes can be created or disappear, and lines may cross. By specifying *preserve\_topology*=True, the result will have the same dimension and number of components as the input; this is significantly slower, however.

`GEOSGeometry.sym_difference` (*other*)

Returns a *GEOSGeometry* combining the points in this geometry not in other, and the points in other not in this geometry.

`GEOSGeometry.union` (*other*)

Returns a *GEOSGeometry* representing all the points in this geometry and the other.

## Topological Properties

`GEOSGeometry.boundary`

Returns the boundary as a newly allocated Geometry object.

`GEOSGeometry.centroid`

Returns a *Point* object representing the geometric center of the geometry. The point is not guaranteed to be on the interior of the geometry.

**GEOSGeometry.convex\_hull**

Returns the smallest *Polygon* that contains all the points in the geometry.

**GEOSGeometry.envelope**

Returns a *Polygon* that represents the bounding envelope of this geometry. Note that it can also return a *Point* if the input geometry is a point.

**GEOSGeometry.point\_on\_surface**

Computes and returns a *Point* guaranteed to be on the interior of this geometry.

**GEOSGeometry.unary\_union**

Computes the union of all the elements of this geometry.

The result obeys the following contract:

- Unioning a set of *LineStrings* has the effect of fully noding and dissolving the linework.
- Unioning a set of *Polygons* will always return a *Polygon* or *MultiPolygon* geometry (unlike *GEOSGeometry.union()*, which may return geometries of lower dimension if a topology collapse occurs).

## Other Properties & Methods

**GEOSGeometry.area**

This property returns the area of the Geometry.

**GEOSGeometry.extent**

This property returns the extent of this geometry as a 4-tuple, consisting of (xmin, ymin, xmax, ymax).

**GEOSGeometry.clone()**

This method returns a *GEOSGeometry* that is a clone of the original.

**GEOSGeometry.distance(*geom*)**

Returns the distance between the closest points on this geometry and the given *geom* (another *GEOSGeometry* object).

---

**Note:** GEOS distance calculations are linear – in other words, GEOS does not perform a spherical calculation even if the SRID specifies a geographic coordinate system.

---

**GEOSGeometry.length**

Returns the length of this geometry (e.g., 0 for a *Point*, the length of a *LineString*, or the circumference of a *Polygon*).

**GEOSGeometry.prepared**

Returns a GEOS PreparedGeometry for the contents of this geometry. PreparedGeometry objects are optimized for the contains, intersects, covers, crosses, disjoint, overlaps, touches and within operations. Refer to the *Prepared Geometries* documentation for more information.

**GEOSGeometry.srs**

Returns a *SpatialReference* object corresponding to the SRID of the geometry or None.

---

**Note:** Requires GDAL.

---

**GEOSGeometry.transform(*ct*, *clone=False*)**

Transforms the geometry according to the given coordinate transformation parameter (*ct*), which may be an integer SRID, spatial reference WKT string, a PROJ.4 string, a *SpatialReference* object, or a

*CoordTransform* object. By default, the geometry is transformed in-place and nothing is returned. However if the `clone` keyword is set, then the geometry is not modified and a transformed clone of the geometry is returned instead.

---

**Note:** Requires GDAL. Raises *GEOSException* if GDAL is not available or if the geometry's SRID is `None` or less than 0. It doesn't impose any constraints on the geometry's SRID if called with a *CoordTransform* object.

In previous versions, it required the geometry's SRID to be a positive integer even if it was called with a *CoordTransform* object.

---

## Point

**class Point** (*x=None, y=None, z=None, srid=None*)

*Point* objects are instantiated using arguments that represent the component coordinates of the point or with a single sequence coordinates. For example, the following are equivalent:

```
>>> pnt = Point(5, 23)
>>> pnt = Point([5, 23])
```

Empty *Point* objects may be instantiated by passing no arguments or an empty sequence. The following are equivalent:

```
>>> pnt = Point()
>>> pnt = Point([])
```

In previous versions, an empty *Point* couldn't be instantiated.

## LineString

**class LineString** (*\*args, \*\*kwargs*)

*LineString* objects are instantiated using arguments that are either a sequence of coordinates or *Point* objects. For example, the following are equivalent:

```
>>> ls = LineString((0, 0), (1, 1))
>>> ls = LineString(Point(0, 0), Point(1, 1))
```

In addition, *LineString* objects may also be created by passing in a single sequence of coordinate or *Point* objects:

```
>>> ls = LineString( ((0, 0), (1, 1)) )
>>> ls = LineString( [Point(0, 0), Point(1, 1)] )
```

Empty *LineString* objects may be instantiated by passing no arguments or an empty sequence. The following are equivalent:

```
>>> ls = LineString()
>>> ls = LineString([])
```

In previous versions, an empty *LineString* couldn't be instantiated.

### closed

Returns whether or not this *LineString* is closed.

## LinearRing

**class LinearRing** (\*args, \*\*kwargs)

LinearRing objects are constructed in the exact same way as *LineString* objects, however the coordinates must be *closed*, in other words, the first coordinates must be the same as the last coordinates. For example:

```
>>> ls = LinearRing((0, 0), (0, 1), (1, 1), (0, 0))
```

Notice that (0, 0) is the first and last coordinate – if they were not equal, an error would be raised.

## Polygon

**class Polygon** (\*args, \*\*kwargs)

Polygon objects may be instantiated by passing in parameters that represent the rings of the polygon. The parameters must either be *LinearRing* instances, or a sequence that may be used to construct a *LinearRing*:

```
>>> ext_coords = ((0, 0), (0, 1), (1, 1), (1, 0), (0, 0))
>>> int_coords = ((0.4, 0.4), (0.4, 0.6), (0.6, 0.6), (0.6, 0.4), (0.4, 0.4))
>>> poly = Polygon(ext_coords, int_coords)
>>> poly = Polygon(LinearRing(ext_coords), LinearRing(int_coords))
```

In previous versions, an empty Polygon couldn't be instantiated.

**classmethod from\_bbox** (bbox)

Returns a polygon object from the given bounding-box, a 4-tuple comprising (xmin, ymin, xmax, ymax).

**num\_interior\_rings**

Returns the number of interior rings in this geometry.

---

## Comparing Polygons

Note that it is possible to compare Polygon objects directly with < or >, but as the comparison is made through Polygon's *LineString*, it does not mean much (but is consistent and quick). You can always force the comparison with the *area* property:

```
>>> if poly_1.area > poly_2.area:
>>>     pass
```

---

## Geometry Collections

### MultiPoint

**class MultiPoint** (\*args, \*\*kwargs)

MultiPoint objects may be instantiated by passing in *Point* objects as arguments, or a single sequence of *Point* objects:

```
>>> mp = MultiPoint(Point(0, 0), Point(1, 1))
>>> mp = MultiPoint((Point(0, 0), Point(1, 1)) )
```

In previous versions, an empty MultiPoint couldn't be instantiated.

## MultiLineString

**class MultiLineString** (\*args, \*\*kwargs)

MultiLineString objects may be instantiated by passing in *LineString* objects as arguments, or a single sequence of *LineString* objects:

```
>>> ls1 = LineString((0, 0), (1, 1))
>>> ls2 = LineString((2, 2), (3, 3))
>>> mls = MultiLineString(ls1, ls2)
>>> mls = MultiLineString([ls1, ls2])
```

In previous versions, an empty MultiLineString couldn't be instantiated.

### merged

Returns a *LineString* representing the line merge of all the components in this MultiLineString.

### closed

Returns True if and only if all elements are closed. Requires GEOS 3.5.

## MultiPolygon

**class MultiPolygon** (\*args, \*\*kwargs)

MultiPolygon objects may be instantiated by passing in *Polygon* objects as arguments, or a single sequence of *Polygon* objects:

```
>>> p1 = Polygon( ((0, 0), (0, 1), (1, 1), (0, 0)) )
>>> p2 = Polygon( ((1, 1), (1, 2), (2, 2), (1, 1)) )
>>> mp = MultiPolygon(p1, p2)
>>> mp = MultiPolygon([p1, p2])
```

In previous versions, an empty MultiPolygon couldn't be instantiated.

### cascaded\_union

Deprecated since version 1.10: Use the *GEOSGeometry.unary\_union* property instead.

Returns a *Polygon* that is the union of all of the component polygons in this collection. The algorithm employed is significantly more efficient (faster) than trying to union the geometries together individually.<sup>2</sup>

## GeometryCollection

**class GeometryCollection** (\*args, \*\*kwargs)

GeometryCollection objects may be instantiated by passing in other *GEOSGeometry* as arguments, or a single sequence of *GEOSGeometry* objects:

```
>>> poly = Polygon( ((0, 0), (0, 1), (1, 1), (0, 0)) )
>>> gc = GeometryCollection(Point(0, 0), MultiPoint(Point(0, 0), Point(1, 1)),
↳poly)
>>> gc = GeometryCollection((Point(0, 0), MultiPoint(Point(0, 0), Point(1, 1))),
↳poly)
```

In previous versions, an empty GeometryCollection couldn't be instantiated.

---

<sup>2</sup> For more information, read Paul Ramsey's blog post about (Much) Faster Unions in PostGIS 1.4 and Martin Davis' blog post on Fast polygon merging in JTS using Cascaded Union.

## Prepared Geometries

In order to obtain a prepared geometry, just access the `GEOSGeometry.prepared` property. Once you have a `PreparedGeometry` instance its spatial predicate methods, listed below, may be used with other `GEOSGeometry` objects. An operation with a prepared geometry can be orders of magnitude faster – the more complex the geometry that is prepared, the larger the speedup in the operation. For more information, please consult the [GEOS wiki page on prepared geometries](#).

For example:

```
>>> from django.contrib.gis.geos import Point, Polygon
>>> poly = Polygon.from_bbox((0, 0, 5, 5))
>>> prep_poly = poly.prepared
>>> prep_poly.contains(Point(2.5, 2.5))
True
```

## PreparedGeometry

### class PreparedGeometry

All methods on `PreparedGeometry` take an `other` argument, which must be a `GEOSGeometry` instance.

`contains` (*other*)

`contains_properly` (*other*)

`covers` (*other*)

`crosses` (*other*)

`disjoint` (*other*)

`intersects` (*other*)

`overlaps` (*other*)

`touches` (*other*)

`within` (*other*)

## Geometry Factories

### fromfile (*file\_h*)

**Parameters** `file_h` (a Python `file` object or a string path to the file) – input file that contains spatial data

**Return type** a `GEOSGeometry` corresponding to the spatial data in the file

Example:

```
>>> from django.contrib.gis.geos import fromfile
>>> g = fromfile('/home/bob/geom.wkt')
```

### fromstr (*string*, *srid=None*)

#### Parameters

- `string` (*string*) – string that contains spatial data

- `srid(int)` – spatial reference identifier

**Return type** a *GEOSGeometry* corresponding to the spatial data in the string

`fromstr(string, srid)` is equivalent to `GEOSGeometry(string, srid)`.

Example:

```
>>> from django.contrib.gis.geos import fromstr
>>> pnt = fromstr('POINT(-90.5 29.5)', srid=4326)
```

## I/O Objects

### Reader Objects

The reader I/O classes simply return a *GEOSGeometry* instance from the WKB and/or WKT input given to their `read(geom)` method.

#### class *WKBReader*

Example:

```
>>> from django.contrib.gis.geos import WKBReader
>>> wkb_r = WKBReader()
>>> wkb_r.read('01010000000000000000000000F03F000000000000F03F')
<Point object at 0x103a88910>
```

#### class *WKTReader*

Example:

```
>>> from django.contrib.gis.geos import WKTReader
>>> wkt_r = WKTReader()
>>> wkt_r.read('POINT(1 1)')
<Point object at 0x103a88b50>
```

### Writer Objects

All writer objects have a `write(geom)` method that returns either the WKB or WKT of the given geometry. In addition, *WKBWriter* objects also have properties that may be used to change the byte order, and or include the SRID value (in other words, EWKB).

#### class *WKBWriter* (*dim=2*)

*WKBWriter* provides the most control over its output. By default it returns OGC-compliant WKB when its `write` method is called. However, it has properties that allow for the creation of EWKB, a superset of the WKB standard that includes additional information. See the *WKBWriter.outdim* documentation for more details about the `dim` argument.

The ability to pass the `dim` argument to the constructor was added.

**write(geom)**

Returns the WKB of the given geometry as a Python `buffer` object. Example:

```
>>> from django.contrib.gis.geos import Point, WKBWriter
>>> pnt = Point(1, 1)
>>> wkb_w = WKBWriter()
>>> wkb_w.write(pnt)
<read-only buffer for 0x103a898f0, size -1, offset 0 at 0x103a89930>
```

**write\_hex** (*geom*)

Returns WKB of the geometry in hexadecimal. Example:

```
>>> from django.contrib.gis.geos import Point, WKBWriter
>>> pnt = Point(1, 1)
>>> wkb_w = WKBWriter()
>>> wkb_w.write_hex(pnt)
'010100000000000000000000F03F000000000000F03F'
```

**byteorder**

This property may be set to change the byte-order of the geometry representation.

Byteorder Value	Description
0	Big Endian (e.g., compatible with RISC systems)
1	Little Endian (e.g., compatible with x86 systems)

Example:

```
>>> from django.contrib.gis.geos import Point, WKBWriter
>>> wkb_w = WKBWriter()
>>> pnt = Point(1, 1)
>>> wkb_w.write_hex(pnt)
'010100000000000000000000F03F000000000000F03F'
>>> wkb_w.byteorder = 0
'00000000013FF000000000000003FF0000000000000'
```

**outdim**

This property may be set to change the output dimension of the geometry representation. In other words, if you have a 3D geometry then set to 3 so that the Z value is included in the WKB.

Outdim Value	Description
2	The default, output 2D WKB.
3	Output 3D WKB.

Example:

```
>>> from django.contrib.gis.geos import Point, WKBWriter
>>> wkb_w = WKBWriter()
>>> wkb_w.outdim
2
>>> pnt = Point(1, 1, 1)
>>> wkb_w.write_hex(pnt) # By default, no Z value included:
'010100000000000000000000F03F000000000000F03F'
>>> wkb_w.outdim = 3 # Tell writer to include Z values
>>> wkb_w.write_hex(pnt)
'010100008000000000000000F03F000000000000F03F000000000000F03F'
```

**srid**

Set this property with a boolean to indicate whether the SRID of the geometry should be included with the WKB representation. Example:

```
>>> from django.contrib.gis.geos import Point, WKBWriter
>>> wkb_w = WKBWriter()
>>> pnt = Point(1, 1, srid=4326)
>>> wkb_w.write_hex(pnt) # By default, no SRID included:
```

```
'01010000000000000000000000000000F03F00000000000000F03F'  
>>> wkb_w.srid = True # Tell writer to include SRID  
>>> wkb_w.write_hex(pnt)  
'0101000020E61000000000000000000000F03F00000000000000F03F'
```

**class** `WKTWriter` (*dim=2, trim=False, precision=None*)

This class allows outputting the WKT representation of a geometry. See the `WKBWriter.outdim`, `trim`, and `precision` attributes for details about the constructor arguments.

The ability to pass the `dim`, `trim`, and `precision` arguments to the constructor was added.

**write** (*geom*)

Returns the WKT of the given geometry. Example:

```
>>> from django.contrib.gis.geos import Point, WKTWriter  
>>> pnt = Point(1, 1)  
>>> wkt_w = WKTWriter()  
>>> wkt_w.write(pnt)  
'POINT (1.0000000000000000 1.0000000000000000)'
```

**outdim**

See `WKBWriter.outdim`.

**trim**

This property is used to enable or disable trimming of unnecessary decimals.

```
>>> from django.contrib.gis.geos import Point, WKTWriter  
>>> pnt = Point(1, 1)  
>>> wkt_w = WKTWriter()  
>>> wkt_w.trim  
False  
>>> wkt_w.write(pnt)  
'POINT (1.0000000000000000 1.0000000000000000)'  
>>> wkt_w.trim = True  
>>> wkt_w.write(pnt)  
'POINT (1 1)'
```

**precision**

This property controls the rounding precision of coordinates; if set to `None` rounding is disabled.

```
>>> from django.contrib.gis.geos import Point, WKTWriter  
>>> pnt = Point(1.44, 1.66)  
>>> wkt_w = WKTWriter()  
>>> print(wkt_w.precision)  
None  
>>> wkt_w.write(pnt)  
'POINT (1.4399999999999999 1.6599999999999999)'  
>>> wkt_w.precision = 0  
>>> wkt_w.write(pnt)  
'POINT (1 2)'  
>>> wkt_w.precision = 1  
>>> wkt_w.write(pnt)  
'POINT (1.4 1.7)'
```

## Settings

### GEOS\_LIBRARY\_PATH

A string specifying the location of the GEOS C library. Typically, this setting is only used if the GEOS C library is in a non-standard location (e.g., `/home/bob/lib/libgeos_c.so`).

---

**Note:** The setting must be the *full* path to the C shared library; in other words you want to use `libgeos_c.so`, not `libgeos.so`.

---

## Exceptions

### exception `GEOSException`

The base GEOS exception, indicates a GEOS-related error.

## GDAL API

GDAL stands for **Geospatial Data Abstraction Library**, and is a veritable “Swiss army knife” of GIS data functionality. A subset of GDAL is the **OGR Simple Features Library**, which specializes in reading and writing vector geographic data in a variety of standard formats.

GeoDjango provides a high-level Python interface for some of the capabilities of OGR, including the reading and coordinate transformation of vector spatial data and minimal support for GDAL’s features with respect to raster (image) data.

---

**Note:** Although the module is named `gdal`, GeoDjango only supports some of the capabilities of OGR and GDAL’s raster features at this time.

---

## Overview

### Sample Data

The GDAL/OGR tools described here are designed to help you read in your geospatial data, in order for most of them to be useful you have to have some data to work with. If you’re starting out and don’t yet have any data of your own to use, GeoDjango tests contain a number of simple data sets that you can use for testing. You can download them here:

```
$ wget https://raw.githubusercontent.com/django/django/master/tests/gis_tests/data/
↪cities/cities.{shp,prj,shx,dbf}
$ wget https://raw.githubusercontent.com/django/django/master/tests/gis_tests/data/
↪rasters/raster.tif
```

## Vector Data Source Objects

### `DataSource`

`DataSource` is a wrapper for the OGR data source object that supports reading data from a variety of OGR-supported geospatial file formats and data sources using a simple, consistent interface. Each data source is represented by a

*DataSource* object which contains one or more layers of data. Each layer, represented by a *Layer* object, contains some number of geographic features (*Feature*), information about the type of features contained in that layer (e.g. points, polygons, etc.), as well as the names and types of any additional fields (*Field*) of data that may be associated with each feature in that layer.

**class DataSource** (*ds\_input*, *encoding='utf-8'*)

The constructor for *DataSource* only requires one parameter: the path of the file you want to read. However, OGR also supports a variety of more complex data sources, including databases, that may be accessed by passing a special name string instead of a path. For more information, see the [OGR Vector Formats](#) documentation. The *name* property of a *DataSource* instance gives the OGR name of the underlying data source that it is using.

The optional *encoding* parameter allows you to specify a non-standard encoding of the strings in the source. This is typically useful when you obtain `DjangoUnicodeDecodeError` exceptions while reading field values.

Once you've created your *DataSource*, you can find out how many layers of data it contains by accessing the *layer\_count* property, or (equivalently) by using the `len()` function. For information on accessing the layers of data themselves, see the next section:

```
>>> from django.contrib.gis.gdal import DataSource
>>> ds = DataSource('/path/to/your/cities.shp')
>>> ds.name
'/path/to/your/cities.shp'
>>> ds.layer_count           # This file only contains one layer
1
```

#### **layer\_count**

Returns the number of layers in the data source.

#### **name**

Returns the name of the data source.

## Layer

**class Layer**

*Layer* is a wrapper for a layer of data in a *DataSource* object. You never create a *Layer* object directly. Instead, you retrieve them from a *DataSource* object, which is essentially a standard Python container of *Layer* objects. For example, you can access a specific layer by its index (e.g. `ds[0]` to access the first layer), or you can iterate over all the layers in the container in a `for` loop. The *Layer* itself acts as a container for geometric features.

Typically, all the features in a given layer have the same geometry type. The *geom\_type* property of a layer is an *OGRGeomType* that identifies the feature type. We can use it to print out some basic information about each layer in a *DataSource*:

```
>>> for layer in ds:
...     print('Layer "%s": %i %ss' % (layer.name, len(layer), layer.geom_type.
↪name))
...
Layer "cities": 3 Points
```

The example output is from the *cities* data source, loaded above, which evidently contains one layer, called "cities", which contains three point features. For simplicity, the examples below assume that you've stored that layer in the variable *layer*:

```
>>> layer = ds[0]
```

**name**

Returns the name of this layer in the data source.

```
>>> layer.name
'cities'
```

**num\_feat**

Returns the number of features in the layer. Same as `len(layer)`:

```
>>> layer.num_feat
3
```

**geom\_type**

Returns the geometry type of the layer, as an *OGRGeomType* object:

```
>>> layer.geom_type.name
'Point'
```

**num\_fields**

Returns the number of fields in the layer, i.e the number of fields of data associated with each feature in the layer:

```
>>> layer.num_fields
4
```

**fields**

Returns a list of the names of each of the fields in this layer:

```
>>> layer.fields
['Name', 'Population', 'Density', 'Created']
```

Returns a list of the data types of each of the fields in this layer. These are subclasses of `Field`, discussed below:

```
>>> [ft.__name__ for ft in layer.field_types]
['OFTString', 'OFTReal', 'OFTReal', 'OFTDate']
```

**field\_widths**

Returns a list of the maximum field widths for each of the fields in this layer:

```
>>> layer.field_widths
[80, 11, 24, 10]
```

**field\_precisions**

Returns a list of the numeric precisions for each of the fields in this layer. This is meaningless (and set to zero) for non-numeric fields:

```
>>> layer.field_precisions
[0, 0, 15, 0]
```

**extent**

Returns the spatial extent of this layer, as an *Envelope* object:

```
>>> layer.extent.tuple
(-104.609252, 29.763374, -95.23506, 38.971823)
```

#### **srs**

Property that returns the *SpatialReference* associated with this layer:

```
>>> print(layer.srs)
GEOGCS["GCS_WGS_1984",
  DATUM["WGS_1984",
    SPHEROID["WGS_1984", 6378137, 298.257223563]],
  PRIMEM["Greenwich", 0],
  UNIT["Degree", 0.017453292519943295]]
```

If the *Layer* has no spatial reference information associated with it, *None* is returned.

#### **spatial\_filter**

Property that may be used to retrieve or set a spatial filter for this layer. A spatial filter can only be set with an *OGRGeometry* instance, a 4-tuple extent, or *None*. When set with something other than *None*, only features that intersect the filter will be returned when iterating over the layer:

```
>>> print(layer.spatial_filter)
None
>>> print(len(layer))
3
>>> [feat.get('Name') for feat in layer]
['Pueblo', 'Lawrence', 'Houston']
>>> ks_extent = (-102.051, 36.99, -94.59, 40.00) # Extent for state of Kansas
>>> layer.spatial_filter = ks_extent
>>> len(layer)
1
>>> [feat.get('Name') for feat in layer]
['Lawrence']
>>> layer.spatial_filter = None
>>> len(layer)
3
```

#### **get\_fields()**

A method that returns a list of the values of a given field for each feature in the layer:

```
>>> layer.get_fields('Name')
['Pueblo', 'Lawrence', 'Houston']
```

#### **get\_geoms (geos=False)**

A method that returns a list containing the geometry of each feature in the layer. If the optional argument *geos* is set to *True* then the geometries are converted to *GEOSGeometry* objects. Otherwise, they are returned as *OGRGeometry* objects:

```
>>> [pt.tuple for pt in layer.get_geoms()]
[(-104.609252, 38.255001), (-95.23506, 38.971823), (-95.363151, 29.763374)]
```

#### **test\_capability (capability)**

Returns a boolean indicating whether this layer supports the given capability (a string). Examples of valid capability strings include: 'RandomRead', 'SequentialWrite', 'RandomWrite',

```
'FastSpatialFilter', 'FastFeatureCount', 'FastGetExtent', 'CreateField',
'Transactions', 'DeleteFeature', and 'FastSetNextByIndex'.
```

## Feature

### class Feature

Feature wraps an OGR feature. You never create a `Feature` object directly. Instead, you retrieve them from a `Layer` object. Each feature consists of a geometry and a set of fields containing additional properties. The geometry of a field is accessible via its `geom` property, which returns an `OGRGeometry` object. A `Feature` behaves like a standard Python container for its fields, which it returns as `Field` objects: you can access a field directly by its index or name, or you can iterate over a feature's fields, e.g. in a `for` loop.

#### geom

Returns the geometry for this feature, as an `OGRGeometry` object:

```
>>> city.geom.tuple
(-104.609252, 38.255001)
```

#### get

A method that returns the value of the given field (specified by name) for this feature, **not** a `Field` wrapper object:

```
>>> city.get('Population')
102121
```

#### geom\_type

Returns the type of geometry for this feature, as an `OGRGeomType` object. This will be the same for all features in a given layer and is equivalent to the `Layer.geom_type` property of the `Layer` object the feature came from.

#### num\_fields

Returns the number of fields of data associated with the feature. This will be the same for all features in a given layer and is equivalent to the `Layer.num_fields` property of the `Layer` object the feature came from.

#### fields

Returns a list of the names of the fields of data associated with the feature. This will be the same for all features in a given layer and is equivalent to the `Layer.fields` property of the `Layer` object the feature came from.

#### fid

Returns the feature identifier within the layer:

```
>>> city.fid
0
```

#### layer\_name

Returns the name of the `Layer` that the feature came from. This will be the same for all features in a given layer:

```
>>> city.layer_name
'cities'
```

#### index

A method that returns the index of the given field name. This will be the same for all features in a given layer:

```
>>> city.index('Population')
1
```

## Field

### class Field

#### **name**

Returns the name of this field:

```
>>> city['Name'].name
'Name'
```

#### **type**

Returns the OGR type of this field, as an integer. The `FIELD_CLASSES` dictionary maps these values onto subclasses of `Field`:

```
>>> city['Density'].type
2
```

#### **type\_name**

Returns a string with the name of the data type of this field:

```
>>> city['Name'].type_name
'String'
```

#### **value**

Returns the value of this field. The `Field` class itself returns the value as a string, but each subclass returns the value in the most appropriate form:

```
>>> city['Population'].value
102121
```

#### **width**

Returns the width of this field:

```
>>> city['Name'].width
80
```

#### **precision**

Returns the numeric precision of this field. This is meaningless (and set to zero) for non-numeric fields:

```
>>> city['Density'].precision
15
```

#### **as\_double()**

Returns the value of the field as a double (float):

```
>>> city['Density'].as_double()
874.7
```

**as\_int()**

Returns the value of the field as an integer:

```
>>> city['Population'].as_int()
102121
```

**as\_string()**

Returns the value of the field as a string:

```
>>> city['Name'].as_string()
'Pueblo'
```

**as\_datetime()**

Returns the value of the field as a tuple of date and time components:

```
>>> city['Created'].as_datetime()
(c_long(1999), c_long(5), c_long(23), c_long(0), c_long(0), c_long(0), c_long(0))
```

## Driver

**class Driver** (*dr\_input*)

The `Driver` class is used internally to wrap an OGR `DataSource` driver.

**driver\_count**

Returns the number of OGR vector drivers currently registered.

## OGR Geometries

### OGRGeometry

`OGRGeometry` objects share similar functionality with `GEOSGeometry` objects and are thin wrappers around OGR's internal geometry representation. Thus, they allow for more efficient access to data when using `DataSource`. Unlike its GEOS counterpart, `OGRGeometry` supports spatial reference systems and coordinate transformation:

```
>>> from django.contrib.gis.gdal import OGRGeometry
>>> polygon = OGRGeometry('POLYGON((0 0, 5 0, 5 5, 0 5))')
```

**class OGRGeometry** (*geom\_input, srs=None*)

This object is a wrapper for the `OGR Geometry` class. These objects are instantiated directly from the given `geom_input` parameter, which may be a string containing WKT, HEX, GeoJSON, a buffer containing WKB data, or an `OGRGeomType` object. These objects are also returned from the `Feature.geom` attribute, when reading vector data from `Layer` (which is in turn a part of a `DataSource`).

**classmethod from\_bbox** (*bbox*)

Constructs a `Polygon` from the given bounding-box (a 4-tuple).

**\_\_len\_\_** ()

Returns the number of points in a *LineString*, the number of rings in a *Polygon*, or the number of geometries in a *GeometryCollection*. Not applicable to other geometry types.

**`__iter__()`**

Iterates over the points in a *LineString*, the rings in a *Polygon*, or the geometries in a *GeometryCollection*. Not applicable to other geometry types.

**`__getitem__()`**

Returns the point at the specified index for a *LineString*, the interior ring at the specified index for a *Polygon*, or the geometry at the specified index in a *GeometryCollection*. Not applicable to other geometry types.

**`dimension`**

Returns the number of coordinated dimensions of the geometry, i.e. 0 for points, 1 for lines, and so forth:

```
>> polygon.dimension
2
```

**`coord_dim`**

Returns or sets the coordinate dimension of this geometry. For example, the value would be 2 for two-dimensional geometries.

**`geom_count`**

Returns the number of elements in this geometry:

```
>>> polygon.geom_count
1
```

**`point_count`**

Returns the number of points used to describe this geometry:

```
>>> polygon.point_count
4
```

**`num_points`**

Alias for *point\_count*.

**`num_coords`**

Alias for *point\_count*.

**`geom_type`**

Returns the type of this geometry, as an *OGRGeomType* object.

**`geom_name`**

Returns the name of the type of this geometry:

```
>>> polygon.geom_name
'POLYGON'
```

**`area`**

Returns the area of this geometry, or 0 for geometries that do not contain an area:

```
>>> polygon.area
25.0
```

**envelope**

Returns the envelope of this geometry, as an *Envelope* object.

**extent**

Returns the envelope of this geometry as a 4-tuple, instead of as an *Envelope* object:

```
>>> point.extent
(0.0, 0.0, 5.0, 5.0)
```

**srs**

This property controls the spatial reference for this geometry, or *None* if no spatial reference system has been assigned to it. If assigned, accessing this property returns a *SpatialReference* object. It may be set with another *SpatialReference* object, or any input that *SpatialReference* accepts. Example:

```
>>> city.geom.srs.name
'GCS_WGS_1984'
```

**sr\_id**

Returns or sets the spatial reference identifier corresponding to *SpatialReference* of this geometry. Returns *None* if there is no spatial reference information associated with this geometry, or if an SRID cannot be determined.

**geos**

Returns a *GEOSGeometry* object corresponding to this geometry.

**gml**

Returns a string representation of this geometry in GML format:

```
>>> OGRGeometry('POINT(1 2)').gml
'<gml:Point><gml:coordinates>1,2</gml:coordinates></gml:Point>'
```

**hex**

Returns a string representation of this geometry in HEX WKB format:

```
>>> OGRGeometry('POINT(1 2)').hex
'01010000000000000000000000000000F03F0000000000000040'
```

**json**

Returns a string representation of this geometry in JSON format:

```
>>> OGRGeometry('POINT(1 2)').json
'{"type": "Point", "coordinates": [ 1.000000, 2.000000 ] }'
```

**kml**

Returns a string representation of this geometry in KML format.

**wkb\_size**

Returns the size of the WKB buffer needed to hold a WKB representation of this geometry:

```
>>> OGRGeometry('POINT(1 2)').wkb_size
21
```

**wkb**

Returns a `buffer` containing a WKB representation of this geometry.

**wkt**

Returns a string representation of this geometry in WKT format.

**ewkt**

Returns the EWKT representation of this geometry.

**clone()**

Returns a new *OGRGeometry* clone of this geometry object.

**close\_rings()**

If there are any rings within this geometry that have not been closed, this routine will do so by adding the starting point to the end:

```
>>> triangle = OGRGeometry('LINEARRING (0 0,0 1,1 0)')
>>> triangle.close_rings()
>>> triangle.wkt
'LINEARRING (0 0,0 1,1 0,0 0)'
```

**transform** (*coord\_trans*, *clone=False*)

Transforms this geometry to a different spatial reference system. May take a *CoordTransform* object, a *SpatialReference* object, or any other input accepted by *SpatialReference* (including spatial reference WKT and PROJ.4 strings, or an integer SRID).

By default nothing is returned and the geometry is transformed in-place. However, if the `clone` keyword is set to `True` then a transformed clone of this geometry is returned instead.

**intersects** (*other*)

Returns `True` if this geometry intersects the other, otherwise returns `False`.

**equals** (*other*)

Returns `True` if this geometry is equivalent to the other, otherwise returns `False`.

**disjoint** (*other*)

Returns `True` if this geometry is spatially disjoint to (i.e. does not intersect) the other, otherwise returns `False`.

**touches** (*other*)

Returns `True` if this geometry touches the other, otherwise returns `False`.

**crosses** (*other*)

Returns `True` if this geometry crosses the other, otherwise returns `False`.

**within** (*other*)

Returns `True` if this geometry is contained within the other, otherwise returns `False`.

**contains** (*other*)

Returns `True` if this geometry contains the other, otherwise returns `False`.

**overlaps** (*other*)

Returns `True` if this geometry overlaps the other, otherwise returns `False`.

**boundary ()**

The boundary of this geometry, as a new *OGRGeometry* object.

**convex\_hull**

The smallest convex polygon that contains this geometry, as a new *OGRGeometry* object.

**difference ()**

Returns the region consisting of the difference of this geometry and the other, as a new *OGRGeometry* object.

**intersection ()**

Returns the region consisting of the intersection of this geometry and the other, as a new *OGRGeometry* object.

**sym\_difference ()**

Returns the region consisting of the symmetric difference of this geometry and the other, as a new *OGRGeometry* object.

**union ()**

Returns the region consisting of the union of this geometry and the other, as a new *OGRGeometry* object.

**tuple**

Returns the coordinates of a point geometry as a tuple, the coordinates of a line geometry as a tuple of tuples, and so forth:

```
>>> OGRGeometry('POINT (1 2)').tuple
(1.0, 2.0)
>>> OGRGeometry('LINESTRING (1 2,3 4)').tuple
((1.0, 2.0), (3.0, 4.0))
```

**coords**

An alias for *tuple*.

**class Point****x**

Returns the X coordinate of this point:

```
>>> OGRGeometry('POINT (1 2)').x
1.0
```

**y**

Returns the Y coordinate of this point:

```
>>> OGRGeometry('POINT (1 2)').y
2.0
```

**z**

Returns the Z coordinate of this point, or None if the point does not have a Z coordinate:

```
>>> OGRGeometry('POINT (1 2 3)').z
3.0
```

**class LineString****x**

Returns a list of X coordinates in this line:

```
>>> OGRGeometry('LINESTRING (1 2,3 4)').x
[1.0, 3.0]
```

**y**

Returns a list of Y coordinates in this line:

```
>>> OGRGeometry('LINESTRING (1 2,3 4)').y
[2.0, 4.0]
```

**z**

Returns a list of Z coordinates in this line, or None if the line does not have Z coordinates:

```
>>> OGRGeometry('LINESTRING (1 2 3,4 5 6)').z
[3.0, 6.0]
```

**class Polygon****shell**

Returns the shell or exterior ring of this polygon, as a LinearRing geometry.

**exterior\_ring**

An alias for *shell*.

**centroid**

Returns a *Point* representing the centroid of this polygon.

**class GeometryCollection****add (geom)**

Adds a geometry to this geometry collection. Not applicable to other geometry types.

**OGRGeomType****class OGRGeomType (type\_input)**

This class allows for the representation of an OGR geometry type in any of several ways:

```
>>> from django.contrib.gis.gdal import OGRGeomType
>>> gt1 = OGRGeomType(3)           # Using an integer for the type
>>> gt2 = OGRGeomType('Polygon')  # Using a string
>>> gt3 = OGRGeomType('POLYGON')  # It's case-insensitive
>>> print(gt1 == 3, gt1 == 'Polygon') # Equivalence works w/non-OGRGeomType_
↪objects
True True
```

**name**

Returns a short-hand string form of the OGR Geometry type:

```
>>> gt1.name
'Polygon'
```

#### **num**

Returns the number corresponding to the OGR geometry type:

```
>>> gt1.num
3
```

#### **django**

Returns the Django field type (a subclass of GeometryField) to use for storing this OGR type, or None if there is no appropriate Django type:

```
>>> gt1.django
'PolygonField'
```

## **Envelope**

### **class Envelope** (\*args)

Represents an OGR Envelope structure that contains the minimum and maximum X, Y coordinates for a rectangle bounding box. The naming of the variables is compatible with the OGR Envelope C structure.

#### **min\_x**

The value of the minimum X coordinate.

#### **min\_y**

The value of the maximum X coordinate.

#### **max\_x**

The value of the minimum Y coordinate.

#### **max\_y**

The value of the maximum Y coordinate.

#### **ur**

The upper-right coordinate, as a tuple.

#### **ll**

The lower-left coordinate, as a tuple.

#### **tuple**

A tuple representing the envelope.

#### **wkt**

A string representing this envelope as a polygon in WKT format.

#### **expand\_to\_include** (\*args)

## Coordinate System Objects

### SpatialReference

**class SpatialReference** (*srs\_input*)

Spatial reference objects are initialized on the given `srs_input`, which may be one of the following:

- OGC Well Known Text (WKT) (a string)
- EPSG code (integer or string)
- PROJ.4 string
- A shorthand string for well-known standards ('WGS84', 'WGS72', 'NAD27', 'NAD83')

Example:

```
>>> wgs84 = SpatialReference('WGS84') # shorthand string
>>> wgs84 = SpatialReference(4326) # EPSG code
>>> wgs84 = SpatialReference('EPSG:4326') # EPSG string
>>> proj4 = '+proj=longlat +ellps=WGS84 +datum=WGS84 +no_defs '
>>> wgs84 = SpatialReference(proj4) # PROJ.4 string
>>> wgs84 = SpatialReference("GEOGCS['WGS 84',
DATUM['WGS_1984',
    SPHEROID['WGS 84',6378137,298.257223563,
        AUTHORITY['EPSG','7030']],
    AUTHORITY['EPSG','6326']],
PRIMEM['Greenwich',0,
    AUTHORITY['EPSG','8901']],
UNIT['degree',0.01745329251994328,
    AUTHORITY['EPSG','9122']],
AUTHORITY['EPSG','4326'])" # OGC WKT
```

**\_\_getitem\_\_** (*target*)

Returns the value of the given string attribute node, None if the node doesn't exist. Can also take a tuple as a parameter, (*target*, *child*), where *child* is the index of the attribute in the WKT. For example:

```
>>> wkt = 'GEOGCS["WGS 84", DATUM["WGS_1984, ... AUTHORITY["EPSG","4326"]]'
>>> srs = SpatialReference(wkt) # could also use 'WGS84', or 4326
>>> print(srs['GEOGCS'])
WGS 84
>>> print(srs['DATUM'])
WGS_1984
>>> print(srs['AUTHORITY'])
EPSG
>>> print(srs['AUTHORITY', 1]) # The authority value
4326
>>> print(srs['TOWGS84', 4]) # the fourth value in this wkt
0
>>> print(srs['UNIT|AUTHORITY']) # For the units authority, have to use the pipe_
↪symbol.
EPSG
>>> print(srs['UNIT|AUTHORITY', 1]) # The authority value for the units
9122
```

**attr\_value** (*target*, *index=0*)

The attribute value for the given target node (e.g. 'PROJCS'). The index keyword specifies an index of the child node to return.

**auth\_name** (*target*)

Returns the authority name for the given string target node.

**auth\_code** (*target*)

Returns the authority code for the given string target node.

**clone** ()

Returns a clone of this spatial reference object.

**identify\_epsg** ()

This method inspects the WKT of this `SpatialReference` and will add EPSG authority nodes where an EPSG identifier is applicable.

**from\_esri** ()

Morphs this `SpatialReference` from ESRI's format to EPSG

**to\_esri** ()

Morphs this `SpatialReference` to ESRI's format.

**validate** ()

Checks to see if the given spatial reference is valid, if not an exception will be raised.

**import\_epsg** (*epsg*)

Import spatial reference from EPSG code.
